The Use of the X-ray in Fractures.—Our attention has been again called to the interesting subject of the X-ray in the diagnosis and prognosis of fractures by an excellent exposition of the subject in the *British Medical Journal*, June 8th, from the pen of Golding-Bird, one of the Guy's Hospital surgeons. That the X-ray has oftentimes produced confusion and discomfort in the surgical mind and a marked discontent in the mind of the patient is too true to require repetition. But the mistake should not be made of depriving this most wonderful discovery of its proper place among diagnostic means. Our confusion and our distrust have in most instances been shown to be due to some mistake in technique or to an improper interpretation of the skiagraph. The rays have frequently shown undoubtedly that a fracture was present when none was suspected, but it must not be forgotten that to an inexperienced eye a fracture would oftentimes seem to be present when none existed. The X-ray must be looked upon as *one* of the means of diagnosis, and we should use it just as we try to elicit crepitus and deformity. That it is too often neglected in cases of doubt is very true. It is, however, as great a mistake to go to the extreme of trusting absolutely to the skiagraph, as it would be to neglect entirely the clinical side of other conditions and trust the laboratory altogether for our diagnosis. In cases of difficulty and doubt, Golding-Bird tells us it is our duty to use the X-ray always, but that the result "should be received with caution, and only after the interpretation by some one whose experience warrants his speaking with authority." The author also shows us that the surgeon who would judge his results by what the X-ray shows is doomed to disappointment, for when the limb comes off of the splint the skiagraph will not infrequently show great mal-adaptation of fragments and a condition suggestive of failure. If however, another skiagraph is made after the lapse of considerable time when callus has been absorbed, a wonderful improvement is shown. In no sense is the X-ray to be used as a prognostic measure after fracture. Function is far more important than perfect coaptation of fragments. It has often seemed that too much attention is paid to obtaining

a beautiful bone scar and not enough to restoration of function, which, after all, is the thing at which we should aim. The general practitioner has not as yet come to realize the great advance made in the last few years in the treatment of troublesome fractures, particularly those about the elbow and wrist joints. Cases with perfectly set and firmly united bones continue to turn up at our hospitals with ankylosed joints and tendons, when early motion and massage would have saved the patient much pain and loss of time.

If patients themselves examine the skiagraphs, Golding-Bird rightly suggests that they should always be told that when the splint is removed the X-ray will show the bones much as they were at first, but that this fact will not interfere with the function of the part, and that a skiagraph made a number of months later will show an entirely different picture. As an evidence in court, the X-ray should not be admitted as a factor in prognosis and only in diagnosis when corroborated by other symptoms.

The Present Status of Plague in San Francisco.—We have, in some of our previous issues, referred editorially to the plague situation in San Francisco. In these editorials we have endeavored to point out the importance of the recognition of the existence of plague in this country, and to urge the use of such measures of removal and prevention as circumstances warrant. Although the existence of plague was established beyond a doubt by the local health authorities of San Francisco, and their conclusions were verified by all of the leading pathologists and bacteriologists of that city, yet in the face of doubts thrown upon their conclusions by the hostile State Board of Health and State officials occupying high places, the appointment of a national commission for the purpose of final judgment seemed entirely justifiable. Doubtless very few of the physicians of the East who have read reports of the plague situation in San Francisco, in the newspapers and medical journals, were surprised at the report of the National Commission. They were convinced that the plague had prevailed in the Chinese quarter for at least a year.

The present status is at least unfortunate. There is reason to believe that a respectable fraction of the intelligent people of San Francisco still doubts the combined decisions of the City Health Board, the local bacteriologists and pathologists, and the National Commission. In addition to the laity which has remained unconvinced, it would appear that certain prominent medical men hold and promulgate contrary views. It is proper to state that these physicians had committed themselves in public to the non-plague character of the epidemic disease at an early date in the course of the controversy, and before the arrival of the National Commission. There is no reason to believe that their views have been based upon careful study. They seem to have been arrived at extemporaneously, and as such have been held with great tenacity, and in spite of convincing evidence to the contrary.

It has been intimated that this unfortunate situation is in large part the result of the delay observed by the Treasury Department in publishing the official report of the Plague Commission. That there was such a delay is of course well known, and we criticised it quite freely in these columns; but it does not seem clear to us, upon further inquiry, that prompt and immediate publication would have changed the heretical views held by the physicians alluded to. On the contrary, it is claimed that good was accomplished by withholding the official announcement of the existence of the disease in San Francisco in view of the nervous tension evident in the States immediately bordering upon California. Texas had already quarantined against California; other States might have been expected to follow such example, and it is doubtful whether the exigencies of the situation demanded such a course; while in the interval before the publication of the report, time seems to have been afforded for launching into successful operation the somewhat complex and difficult machinery through which regular medical inspection, care, and treatment of established and suspicious cases might be provided. This action, in which all interested parties joined, offered a pledge of security to the adjoining States, and probably obviated the hasty and unnecessarily violent action of quarantining the State of California, and thus interfering with the industry, commerce, and travel of the State.

Looked at, therefore, without heat, and weighed with caution, the action of the Secretary of the Treasury and the Surgeon General of the Marine Hospital Service, while, perhaps, a severe temporary trial to those brave advocates of science in San Francisco who were held up to ridicule and abuse by the newspapers, must, we think, in the end be

regarded as justified by the local situation, and, moreover, cannot be held to have endangered the health of the State, or diminished the high gratitude due to the City officials and the disinterested scientists in San Francisco, who carried the burden of the situation well during the troublous times of the controversy.

Insects as Factors in the Conveyance of Disease.—Surgeon General Wyman, of the United States Marine Hospital Service, has recently issued a circular directing the attention of the medical officers of that service to the great importance of this subject. It has seemed to us (although we may be mistaken), that the marine and military authorities pay more attention to this subject than do municipal and other civil functionaries. We know that right here in Philadelphia the "plague of flies" is not well combated in some of our large hospitals. To go through some of our wards on a mid-summer's day is to be harrowed not more by the vision of disease than by the all-pervading curse of insects. Flies are not the only sinners. Fleas, bed-bugs and mosquitoes do their share in the general bedevilment of the sick and injured.

This is no longer a mere question of comfort. It is one even of life and death. As Dr. Wyman says, there is now no doubt as to the relation of the mosquito to malaria and filariasis. Plague, according to Simon, is transmitted from the rat to man by the flea. Typhoid fever and cholera are possibly conveyed by flies which become contaminated by the excreta. Again, yellow fever, according to some, but not all, observers, is transmitted by the mosquito. The best way to kill flies and mosquitoes is by sulphur fumigation. Mosquitoes should be prevented from breeding by draining or covering all collections of standing water, or by covering the surface with petroleum. In this city of Philadelphia fly-screens and mosquito-netting should be used universally. No hospital should be considered well equipped that leaves doors and windows unguarded. Excreta should be kept away from flies.

A Menace to Colorado.—In the early days Colorado was rather proud of her pre-eminence as a health resort—an honor which the State clearly deserved. All was well with the young and nascent Commonwealth so long as invalids flocked thitherward and paid their way and supported hotels and doctors and helped to build up the State. The commercial aspects of the situation alone seemed to appeal to the inhabitants, and they saw nothing but prosperity in the arriving tide of valetudinarians. This optimism, however, has suffered some decline of recent years, and evidence is not lacking that some people in Colorado do not relish a further in-

flux of invalids—and especially consumptives—into the State. There is a distinct pessimistic note in their complaints; they think (with some show of reason) that a tuberculous population is not to be desired. They especially deplore the permanent settlement and breeding of consumptives within their borders. Mr. H. A. Crafts, in a recent paper (*Popular Science*, July, 1901), says that "the doctors, undertakers and drug stores have had a harvest in Colorado," but as for the rest of the people, they begin to realize that their zeal for consumptives has run away with their common sense. Statistics seem to prove that deaths from tuberculosis contracted in Colorado are rapidly on the increase. In Denver alone deaths from this dread disease contracted in the State increased from 49 in 1893 to 99 in 1898—an increase of more than 100 per cent. in five years. Of the entire mortality of Denver, the percentage of deaths from tuberculosis increased from 11.23 in 1893 to 19.77 in 1898—but the number of imported cases among these is not stated.

The cry of alarm is evidently raised because of the belief that tuberculosis is a contagious disease. Hence it is not altogether unreasonable. But we should like to ask whether this cry about the contagiousness of consumption is not somewhat over-loud? That the disease is due to a specific bacillus is well enough established, but that it is actively infectious by personal contact in ordinary social life is not sufficiently proven. Let us recall the example of malaria, and probably that, too, of yellow fever.

No Yellow Fever in Havana.—It is gratifying to read the report from Havana that there is no yellow fever in that city, and that since March 1st only one death from the disease has occurred, and that the last case was treated on May 7th. According to the dispatch, from which we quote, never before has Havana been free from yellow fever during the same period. So elated are the authorities over this state of things that they have decided to ask that the quarantine in New York against Cuba be raised as being unnecessary. Major Gorgas, the chief sanitary officer, is reported as having endorsed this request, which seems reasonable enough.

While all this is extremely pleasing, it hardly justifies the conclusion, which some seek to draw from it, that this exemption proves the truth of the mosquito theory. Yellow fever patients in Havana, we are told, have been protected from the bites of mosquitoes by being surrounded by netting, and hence the conclusion is drawn that yellow fever is being controlled. We are rather inclined to give some credit to the general improvement in sanitation which has marked the American administration

in Cuba. We shall, of course, keep a mind open to proof of the mosquito theory, but this proof must be based on something rather more convincing than even this most satisfactory report.

The Fourth of July Sacrifice.—It is sad to think of the goodly number of American boys who, at the time of this writing, being yet in buoyant and exuberant health, shall, ere these lines appear in print, have paid the forfeit of their safety or their lives in the annual fusillade that marks our national holiday. Unless all precedents fail, we are to reap in a few days our seasonal harvest of injury and death. It is useless to moralize about it, or to indulge in direful philippics against the American eagle. Perhaps it is even out of place to try and draw classical parallels and to say that we are like the ancient Athenians who every year paid tribute of their youths to the fabled Minotaur. But even if we are obstinate in our patriotism to the extent of wanting to make a noise about it, we should at least have sense enough to keep firearms out of the hands of children and boys. This year, as heretofore, there will doubtless be a certain amount of Fourth of July tetanus, and almost every case of it will be chargeable to the authorities who neglect to suppress the villainous toy-pistol. As for the older patriots, who insist on firing cannon and dynamite bombs, there is nothing to do but to let them play the fool; but they ought at least to be driven out of the cities and towns and made to express themselves in the open fields. It will not be too late, even when this writing appears in print, to urge a most careful antiseptic treatment of all Fourth of July wounds.

The Influence of Boric Acid, Borax and Formaldehyde on Nutrition and Tissue-Change in Children.—The extensive use of these agents in food, in spite of the energetic efforts of health authorities, makes any information concerning their physiological actions of much interest. The data in this field have been accumulated by many observers and in several ways. Some have experimented merely in test-tubes and flasks studying especially the influence on digestive processes; others have made prolonged studies of the effect on the lower animals when fed with articles containing notable amounts of the preservatives. Both these methods are subject to criticism from the clinical point of view. It is not safe to trust much to negative results obtained in the chemical or physiological laboratory. The human organism is very sensitive and will be unfavorably influenced by conditions which will not disturb the digestion of a starch solution by diastase or the functions of a

small animal. So far as these classes of experiments may be taken as a guide, it appears that neither boric acid, formaldehyde, nor borax exerts any marked influence on ordinary digestion or nutrition.

Important contributions to the subject are found in papers recently published by F. W. Tunnicliffe and O. Rosenheim (*Journal of Hygiene*, April, 1901; *Centralbl. f. Physiolog.*, April 27th, 1901), who have made experiments by feeding apparently healthy and delicate infants with articles containing these preservatives and making careful analytical and other observations as to the effects on nutrition and metabolism. They arrive at the following conclusions, which are not likely to strengthen the hands of those who wish to restrict the use of such agents.

Boric acid in small doses up to one gram per day produces in healthy or delicate children no change in proteid metabolism and no appreciable influence on the assimilation of fat. The body weight is increased. Similarly, borax in 1.5 grams doses per day produces no unfavorable influence on proteid metabolism or assimilation of fat, and the body weight is increased. The amount of dry feces is slightly increased with borax, but not with boric acid. A mixture of boric acid and borax (which has been found to be a better preservative than either alone) is quickly eliminated and does not act unfavorably.

Concerning formaldehyde, the observers find as follows: Formaldehyde added to milk in the proportion of 1 to 5000, or to the entire aliment in proportion of 1 to 6000, has no appreciable influence upon the more important phases of healthy children, but with debilitated children some interference is shown. With these, the quantity of urine and dry feces is increased. The excretion of lecithin is decreased. In no case was any unfavorable influence upon the general health of the children noticed. Neither borax, boric acid nor formaldehyde exerted any antiseptic action upon the intestinal contents. The proportion of formaldehyde used in the milk was considerably in excess of the amount required for ordinary preservation.

Sterility and Fecundity.—At the recent session of the Gynecological and Obstetrical section of the American Medical Association there was probably no more interesting discussion than that which followed the reading of the paper by Dr. George J. Engelmann, of Boston, on "The Increasing Sterility of American Women." Aside from the moral questions that were touched upon by this distinguished statistician, who holds the enviable position of the world's leading authority in his chosen line of investigation, the subject has a bearing of great civic and national importance. Long accus-

tioned as we as a nation have been to consider ourselves a fruitful and progressive people in marked contrast with some of the races of Southern Europe, notably the French, Dr. Engelmann's statement that to-day we are the least fruitful people of the world, comes with appalling frankness. As clearly portrayed by figures that will admit of no controversy, to-day the American born people show a fecundity of less than 2 children per marriage. That is to say, there are barely two children born to a family among those who can claim to be native white Americans. One hundred and more years ago, during the colonial period, the fecundity stood at 6 per marriage, while to-day the general European fecundity is 4.5 per marriage and the French Canadians show the enviable record of 9.1 per marriage. Closely associated with the foregoing statement is the occurrence in Europe of one miscarriage to every 3.3 labors, while in this country a premature expulsion of the ovum occurs in 2.8 labors. Dr. Duff, of Pittsburg, in the animated discussion that followed, emphasized the importance of suppressing the obnoxious advertisements with which the pages of the daily journals teem, and reiterated his belief that dire calamity will fall upon the editorial managements of these journals for admitting such dangerous and nonpatriotic advertisements to the columns of their papers. It is undoubtedly high time that we, as a people, should give this matter of fecundity and sterility careful attention, and still more that we physicians, as the medical guardians of the nation's welfare, take such measures as will tend to suppress vice and encourage the propagation of the race. Dr. Duff's suggestion, which was unanimously endorsed by the meeting, that hereafter the United States Census take note of the paternity (parental nativity), sterility, and fecundity of the people, is a most excellent one. The publication of such records would do much to open the eyes of the best element of the country to the danger that is impending. It is also most important that the blame of sterility be placed where it properly belongs, and that the great frequency of double epididymitis as a causative factor be more generally appreciated. As to the willingness of individuals to assume the important responsibilities of maternity or paternity, this is a phase of the subject that can be influenced only by appealing to the morals of the people. As was suggested by one of the women delegates, an improvement in this direction might be instituted by substituting the questions: "Are you willing to become a mother?" "Are you willing to become a father?" at the time of issuing the marriage license. Failure to acquiesce, in her view, would be deemed ample reason for refusing the license on the ground that legal prostitution could not be countenanced.

Correspondence.

AN EPIDEMIC OF A PECULIAR AND UNFAMILIAR DISEASE OF THE SKIN.

By JAY P. SCHAMBERG, M. D., Philadelphia.

To the Editor of the Philadelphia Medical Journal.

Dear Sir:—It may be of interest to call attention to the existence of a disease, characterized chiefly by cutaneous manifestations which is prevailing in various sections of this city. As far as I have been able to ascertain, the first cases appeared toward the latter part of May. In the Skin Department of the Philadelphia Polyclinic, we have treated some ten or twelve cases during the past few weeks. I am told by several colleagues in charge of skin clinics elsewhere that they have also seen a number of cases of the same character.

The following description is based upon observation of the limited number of cases above referred to, and will doubtless prove to be incomplete when the opportunity is afforded for a more thorough study of this affection.

The disease is characterized by a generalized eruption of erythemo-urticarial spots, many of which acquire at their central summits a pin point to pin head sized vesicle which rapidly becomes pustular. The lesions vary in size from a small pea to a finger nail, are rounded, oval or irregular in shape, and are often quite edematous like the wheals of urticaria. Indeed, the patient is apt to regard the eruption as an attack of "hives." The eruption is usually extensive, involving the trunk, arms and legs, and to a slight extent the face. The back is commonly profusely covered, the shoulders, chest and abdomen being the next most extensive seat of the efflorescence. The forearms frequently exhibit scattered lesions, but the wrists and hands are as a rule free. The thighs and the legs are commonly

itching. This is worse at night, and seriously interferes with sleep. The itching leads to violent scratching, with the consequent production of excoriations and blood crusts, and at times pyogenic infection of the skin.

At the onset of the attack the patient often complains of chills or chilliness, and at times nausea. Mild rigors may recur throughout the course of the next few days, particularly towards evening. The temperature may be elevated from 100° to 102° F. in the beginning, and a rise of one or two degrees may continue for several days. Patients, however, are not inclined to seek their beds. Some patients, although afebrile, complain of malaise and anorexia; others again do not admit being ill at all. There is at times moderate enlargement of the superficial lymphatic glands. The disease seems to run its course in from two to three or four weeks, and apparently is not materially influenced by treatment.

Several members of the same household are commonly affected. These we have observed on one occasion in husband, wife and infant, on another in brother and sister, and several times in husband and wife. As far as we have been able to determine the affection usually begins synchronously in the several members of the same family.

Figure I. Appearances in an average case about the third day.

the seat of a sparse eruption which may develop rather later than on the upper portions of the body. The face may be affected, but the lesions in this region do not seem to last as long as elsewhere.

The eruption is accompanied by the most intolerable

Figure II. Eruption at the end of three weeks showing lesions, excoriations and blood crusts from scratching.

It is too early to say whether or not we are dealing with a disease *sui generis* and it is likewise difficult to state anything definite concerning its nature. The frequency with which the affection attacks several members of the same family would suggest that it is contagious, and possibly of the nature of an acute infectious disease. On the other hand, it must not be forgotten that a common cause, such as the ingestion of a certain foodstuff might simulate a transmissible disease in the production of such a series of cases. It is, perhaps, wisest at this time, to record observations, rather than to elaborate theories. The disease appears to occur in individuals living in widely separated districts of the city.

The eruption is particularly apt to be confounded with ordinary "hives" or urticaria, chicken-pox and scabies. It may be distinguished from "hives" by the much longer duration of the lesions, by the tendency to central vesicula-

tion, the presence of constitutional symptoms, the greater persistence of the attack, and the apparent transmissibility of the affection. It must be admitted, however, that many of the lesions are urticarial in nature.

Chicken-pox may be excluded by the protracted duration of the disease, the smallness of the vesicles, the violence and persistence of the itching, and the great incidence of the disease among adults.

Scabies, or "itch," may be excluded by the freedom of involvement of the hands, by the uniform eruption of erythemo-urticarial lesions surmounted by small vesicles, and by the futility of parasiticide frictions.

THE VIRCHOW FUND.

By A. JACOBI, M. D., of New York.

Editor of the Philadelphia Medical Journal,

Dear Sir:—Some months ago a committee consisting of Dr. Reed, president of the American Medical Association, Dr. Bowditch, president of the Congress of American Physicians and Surgeons, Dr. Welr, president of the New York Academy of Medicine; Dr. Welch, of Johns-Hopkins University, and the writer as secretary, published an appeal to the American medical profession requesting contributions to the Virchow fund which was established ten years ago in honor of Rudolf Virchow's seventieth birthday, which was reached October 13th, 1891. The fund was created for the purpose of fostering biological, anthropological and general medical research. A large German committee, with National committees, formed all over the globe, has undertaken to increase this fund in honor of the coming eightieth birthday of the great medical reformer.

Whatever contributions will be raised, should be sent to Germany on the first day of September in order to be received and acknowledged by the Central Committee in due time. As our former notices may have been overlooked by such as are anxious to show their appreciation of the great master and to aid the cause represented by his lifelong labors, we herewith repeat our appeal.

Reviews.

Die Gicht-Therapie in Karlsbad, by Dr. Richard Sachs
Karlsbad-Wien. Berlin, 1901. Verlag von S. Karger.

This 48-page pamphlet deals with the therapy of gout as conducted in Karlsbad according to modern principles. The first chapter is devoted to the introduction, and discusses the various theories regarding the etiology of gout, with especial reference to the chemical metamorphoses in metabolism. Sachs considers as facts in gout, hyperacidity of the tissue juices due to uric acid, and retarded metabolism; according to these the treatment is divided into three parts, which are discussed separately. (1) Prophylaxis, (2) neutralization of the uric acid, and (3) the treatment directed toward combating the abnormal metabolism. The diet is scientifically arranged. The permissive administration of alkalies from a chemical point of view is wisely guarded against, for it is known that by overloading the blood and the tissue juices with sodium bicarbonate that the latter can easily give rise to the production of insoluble blurate of sodium. It follows, therefore, that alkaline mineral waters should not be used during an attack of gout. There is not a symptom of gout that is not considered in this little work, and with the exception of Karlsbad the doctrines of the author can certainly be employed to advantage by practitioners in any part of the world. It is to be regretted that such valuable treatises are so frequently poorly bound. The author has the happy faculty of saying much in a few words. [M. H. D.]

Lumbar Coccalization; Absence of Analgesia; Prolonged Intoxication. G. Carrière and J. Vanverts. (*L'Echo Medical du Nord*, May 19, 1901. 15me. Année, No. 20).

Carrière and Vanverts report the case of a man, aged 23 years, who was suffering from pain in the right leg, large, multiple adenopathies and emaciation. At the age of 11 the patient had been operated upon, under chloroform anesthesia, for suppurating osteomyelitis of the tibia. Following this operation the patient had vomited for 3

days and had suffered from headache. During the progress of the case an abscess developed in the ankle joint near the tibia. In order to open it and curette the bone it was decided to induce anesthesia by the **subarachnoid injection of 1 cgm. of 1% solution of cocain hydrochlorate**. Four minutes after the administration of the cocain the patient began to vomit, 3 minutes later, on trying to open the abscess, it was found that **sensation was unimpaired**, and after 15 minutes the operation had to be done without anesthesia, but was completed quickly because the bone was not diseased. The patient presented **toxic symptoms**, consisting of violent headache, vomiting and vertigo on standing. These symptoms gradually disappeared so that after 10 days the patient had resumed his usual health. [J. M. S.]

The Pest Epidemic in Egypt from May, 1899 to July, 1900.—The pest appeared first in Alexandria in May, 1899, though it probably existed unknown during the four previous months. In describing this epidemic, Edouard Rist, formerly inspector of the Egyptian Marine and Quarantine Service (*Presse Medicale*, 1901, No. 42) divides the 350,000 inhabitants of Alexandria into three classes, the upper and lower class Europeans, and the natives. Contrary to what is seen in India, the religion of the Egyptians had no effect upon the epidemic. The government hospital is well equipped, having both male and female physicians. All cadavers are examined, and whenever a case seems suspicious, an autopsy is made. The upper class Europeans direct the city, in an advanced manner. The Suez Canal brings vessels from India and pilgrims from Mecca. Port Said is even more exposed than Alexandria. The first cases of pest were not recognized in either city. Most cases were sporadic, without any connection, from one to the other. They were all bubonic. Though the source of the epidemic was sought for most minutely, it could not be found. As many families lived in each house in which a case of pest was discovered, crowds of people were isolated. Out of 992 isolated, only two cases of pest developed. Most of those affected were grocers' and butchers' boys. It was noted that the rats, in the neighborhood in which the first cases appeared, died in great numbers about two weeks before the disease appeared in man. In Alexandria 93 cases occurred, with 45 deaths. 19 of these were only diagnosed after death. Those over six years old, who were isolated, were paid 15 cents a day indemnity. The disinfection was thorough; 90,700 rooms cleaned; 38,259 bags of rags, etc., burned, and 14,674 cloths and 5,822 cushions distributed, to replace those burned or confiscated. 800 people were employed by the sanitary department, and \$180,000 spent. The Yersin bacillus was generally found. From November 1899, to May 1900, there were no cases found. Then the epidemic reappeared. This time the rag-pickers were first affected. It is possible that this outbreak came from Port Said, where the pest had existed for two months. Rist calls especial attention to the fact that the discovery of cases of the pest in a large city is difficult. For four months passed before it was known that pest existed in Alexandria. Yet bacteriological examination will settle the diagnosis. [M. O.]

An Enterococcus the Cause of Dysentery.—K. Lewkowicz (*Przegląd Lekarski*, 1901, Nos. 5-7; *Bohnickowa Gazeta Lekarska*, Vol. XII, No. 11) isolated from the feces of a number of undoubted cases of dysentery a new coccus which he considers as the specific cause of dysentery. The coccus occurs in the form of diplococci (frequently in chains) surrounded by a capsule which is also present in cultures. It differs from the pneumococcus by its larger size and wider capsule. The organism grows only on media containing animal fluids, such as blood serum, ascetic fluid or milk. It is pathogenic to white mice, rabbits (subcutaneously) and guinea pigs. The specificity of the organism rests on the following claims: (1) It was found in all cases observed by the author and Ciechanowski and Nowak (*Centralbl. f. Bakt.*, 1898, p. 445). In two it was present in almost a pure culture. (2) The enterococcus is found also in the metastatic lesions complicating dysentery. (3) The characteristics of its growth point to its parasitic nature. (4) The close relationship to the pneumococcus and streptococcus. (5) Marked pathogenicity to some animals. (6) The predominance of local lesions. [A. R.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Dr. Martin H. Williams, for many years connected with Jefferson Medical College Hospital in various capacities, and at one time chief of the surgical clinic at that hospital, died on June 30 at his home in Philadelphia. He was for two terms a member of the Board of Public Education and at one time Chairman of the Committee on Hygiene in that body. His death will be much regretted by his many friends and confrères.

Dr. J. Ewing Mears, of Philadelphia, has given to the Marion County (Ind.) Medical Society property in Indianapolis valued at \$25,000, on which to erect a home for the society as a memorial to his father, who was a pioneer physician in Indianapolis.

Pathological Society of Philadelphia.—At the meeting of June 27, Dr. William E. Robertson presented two specimens: (1) **Polypoid and ulcerative colitis due to mercury.** The patient had absorbed the mercury while giving injections to another man, the last one having been given 2 years ago. Autopsy showed at least a dozen perforations of the intestine; (2) **Heart and great vessels from a so-called blue baby.** Drs. H. D. Jump and J. D. Steele exhibited specimen of **Polypoid colitis with adenoma of the cecum.** The diagnosis was made post mortem, the patient dying of chronic diarrhea. Double parotitis had developed before death.

Dr. R. C. Rosenberger reported the **pathological findings in a case of trichinosis**, the subject being a patient of Dr. J. Chalmers DaCosta. Examination of muscle removed from the leg of the patient (only one lower extremity being involved) showed encapsulated trichinae, many of which were surrounded by aggregations of lymphoid cells. The literature of the subject was reviewed. One point of interest in the case was the absence of marked eosinophilia. Four blood examinations were made, the eosinophiles ranging from 2.5 to 4%. The statement was made that **eosinophilia is not pathognomonic of trichinosis** as the same condition is noticed in other processes. This statement was borne out by citations from various authors, showing that eosinophilia is present at times in pneumonia, acute articular rheumatism, chorea, leukemia, osteomalacia, emphysema, after injection of tuberculin, and in the presence of many other parasites, as oxyuria, anchylostoma, ascarides, etc. In the discussion Dr. W. M. L. Coplin spoke of the possibility of the recrudescence of lesions. Points in favor of this are that with a local lesion, trichinae may be in other muscles which at the time manifest no symptoms. In this case there was the absence of the marked eosinophilia which is commonly observed in the initial outbreaks of trichinosis. There was also the history of an injury, which cause has produced inflammation of encapsulated but quiescent parasites of other types, as the echinococcus. The fact that pericapsular lymphoid accumulations were present and most marked around the older capsules would indicate that the active inflammatory phenomena present were not of necessity related to living trichinae.

Addition to Allentown Hospital.—The Allentown Hospital has received \$30,000 for the purpose of erecting an additional wing to the hospital for the treatment of surgical cases.

Vital Statistics of Philadelphia for the week ending June 29, 1901.

NEW YORK.

Cornell University Medical College.—The library of the late Dr. Felix Bireh-Hirschfeld, formerly professor of pathological anatomy in the University of Leipzig, has been acquired by purchase by the Cornell University Medical College. It is said to be one of the most valuable libraries in that specialty in the world, and contains about 5,000 volumes. It cost about \$10,000.

Roentgen Society of the United States.—The second regular meeting of this Society will be held in the University of Buffalo, September 10-11, under the presidency of Dr. Heber Roberts, of St. Louis.

Census of Consumptives.—A census of the consumptives in the State of New York is to be begun in about a week by Dr. Daniel Lewis, commissioner of the State Board of Health. It will be the first census of the kind ever undertaken by this State.

NEW ENGLAND.

Yale University.—The annual address in medicine will be delivered by Professor Edmund B. Wilson, Ph. D., of Columbia University, on "The Higher Claims of Minute Research in Biology and Medicine," in the College Street Hall, Yale University, on Tuesday, June 25th, at noon.

WESTERN STATES.

Physicians' Club of Chicago.—At the recent annual meeting of this club, Drs. W. S. Christopher, Joseph Zeisler and G. Frank Lydston were elected directors, and Dr. L. Harrison Mettler was re-elected secretary and treasurer.

The Indian Territory Medical Association.—The Indian Territory Medical Association at its recent semi-annual meeting elected the following officers: President, Dr. G. M. West, of Eufaula; first vice-president, Dr. Louis Baghy, of Vinita; second vice-president, Dr. W. E. Harley, of Durant; secretary and treasurer, Dr. Frederick S. Clinton, of Tulsa. The next meeting will be held in Muskogee next December.

Plague on Board a Steamship at San Diego, Cal.—It has been reported to the Surgeon General of the U. S. Marine Hospital Service that one death occurred on the British steamer Carlisle at Hong Kong before reaching Honolulu, five deaths between Honolulu and San Diego and the last death on June 20, five of the deaths undoubtedly being due to the plague. The report, which is dated June 23, 1901, states that all were well on board at the time the report was sent out and that every precaution has been taken. A later dispatch dated June 24, 1901, states that there were five cases among the crew, that all were Chinese and that all the cases were fatal. The steamer sailed from Hong Kong on May 16 and from Yokohama on May 29. The cook was taken sick on June 6 and died June 9 without any glandular involvement being noticeable. A fireman was taken ill on June 14 and died June 19, with glandular involvement; a donkeyman became ill on June 17 and died June 19, also with glandular swelling; a greaser was taken ill June 17 and died June 21 with in-

involvement of the glands; a sailor was taken ill June 18 and died June 20, also with glandular involvement; a steerage passenger was also found ill at noon June 18 and died at 1.30 P. M. All had high temperature, pain in the back and limbs and in the glandular regions. Dead rats were noticed before the first case of illness. The cases occurred in different portions of the ship. The ship, passengers, crew and effects have been thoroughly disinfected. The dead were buried at sea and their baggage destroyed. On June 24 all were reported well.

SOUTHERN STATES.

The Presbyterian Hospital at Atlanta, Ga., has elected the following medical board: Drs. Marlon McIl, Hull, president, and F. Bates Block, general medicine and diseases of children; Drs. Stephen T. Barnett and Cyrus W. Strickler, general surgery; Drs. Edward C. Davis and James N. Ellis, gynecology and obstetrics; Drs. Walter B. Emery, secretary, and James McFadden Gaston, Jr., genito-urinary surgery; Drs. Arthur G. Hobbs and James M. Crawford, eye, ear, nose and throat; Dr. Michael Hoke, orthopedic surgery, and Drs. Miller B. Hutchinson and John L. McDaniel, disease of skin and nervous system.

Osteopaths Acquitted.—The test case against E.H. Shackelford and G. E. Fout was disposed of in the Hustings Court of Richmond Va., after consuming two days. The jury was instructed to find a verdict for the defendants as the judge stated he was convinced that the defendants did not come under the statute providing for a permit to practice medicine from the State Board of Medical Examiners. Exceptions were taken and the case will now go to the Supreme Court for final decision.

CANADA.

(From Our Regular Correspondent.)

The Rockefeller Fellow at McGill University has been appointed and Dr. W. W. Ford is the fortunate recipient. He will be engaged on some subject in connection with the study of preventable diseases approved by the Committee of the Fund, and will be under the direction and supervision of Professor J. George Adami, who has charge of the department of pathology at McGill, a department which at the present time is one of the brightest and best equipped of the many departments in the university. As the new McGill laboratories are not yet completed, Dr. Ford will spend the next six months at the Pasteur Institute, Paris. Dr. Ford's appointment as well as that of Dr. J. R. McCrae, who was recently made pathologist at the Montreal General Hospital leaves vacant two research and teaching fellowships in the departments of pathology and bacteriology. Applications for these posts will be received by Dr. Ittutan, dean of faculty, up to the 17th of August.

Smallpox in Ontario has not as yet been successfully checked. Within the last two days a new centre has appeared at a small village near the city of Brantford, Ont., where some twenty to thirty cases, mild in character, have been discovered by the provincial bacteriologist, Dr. J. A. Amyot, Toronto. Dr. Hodgetts, of Toronto, has been sent there as a special officer to have charge of the epidemic. During the week ending June 11th, there were some seventeen cases reported throughout the province. During the past year Toronto has had twelve cases, and all but three have been imported cases. Vaccination has been pretty general in this city and the vigilance of the health department along with this fact accounts for the comparative freedom of the city from more infection. Toronto's new smallpox hospital will be ready for occupation in about three weeks. The Dominion Government has appointed Dr. McCully, of Itouneau, Ont., medical officer of quarantine at that place on account of there being a ferry service from Cleveland to Itouneau. Collectors and subcollectors of customs on Lake Erie have been warned to keep a sharp lookout for vessels coming from the Ohio port.

Manitoba University is progressing at a rapid rate. Four hundred and seventy-five students wrote at the spring examinations in arts, medicine and law, showing that this, the youngest university in Canada, is doing good work in the west. Last January, the university opened its new science building, costing \$60,000, where the science faculty now lecture to classes formed of the five affiliated colleges. The university receives a very small grant from the provincial government, but retains the right to appoint its professors. The university possesses 150,000 acres of the Manitoba prairie lands, granted by the Dominion Government, which are now valued at from \$750,000 to \$1,000,000

and which are constantly rising in value. It was from the proceeds of the sales of portions of these lands that the science building was erected.

Drinking is on the Decrease in Ontario.—In 1889 the convictions for drunkenness reported in Ontario amounted to 4,797; but in 1899, this had dropped to 1,892, a decrease of 2,905, or over 60 per cent. In 1889 there was one conviction for drunkenness for every 295 persons and for 1899 one for every 826 and the figures indicate that between these years the reduction was progressive. The number of persons to each conviction in the provinces of Canada for the year 1899 is as follows: Ontario, 826; Quebec, 461; Nova Scotia, 448; New Brunswick, 253; Manitoba, 355; British Columbia, 207; Prince Edward Island, 341, and the Territories, 180.

The Hospital Surgeons for the Coming Year in the Hospitals of Toronto were appointed on the 28th of June and, for the first time in the history of the Toronto hospitals, women physicians have received appointments. The appointment of Dr. Helen MacMurchy to the staff of the General Hospital, following on the selection of Dr. Margaret MacCallum for a position on the resident staff of the Hospital for Sick Children seems to indicate that the women surgeons have found a permanent footing in the hospitals of Toronto. A third woman is spoken for St. Michael's hospital. The members of the new staff of Toronto General Hospital are as follows: From Toronto University graduates, Drs. F. A. Cleland, W. H. Cronyn, H. S. Hutchinson, A. J. MacDougal and J. H. Trout; from Trinity Medical College, Drs. Duncan Anderson, James E. Martin, W. J. MacDonald, E. S. Ryerson and W. G. Collison. To St. Michael's staff, Drs. P. W. O'Brien, R. H. Parent and C. R. Elliott.

Infant Mortality in Montreal has commenced somewhat earlier this year than in previous years and the matter is giving the Health Committee of that city no little concern. For the week ending June 22d there were reported ninety-one deaths amongst infants as against sixty-four for the corresponding week of last year and even the latter number was at that time thought excessive. Out of 100 cities in America from which statistics could be secured, Three Rivers, Que., has the highest death rate, while Hamilton, Ont., has the smallest, the figures for the former being 36.1 per thousand, while for the latter they are put down at 12.9. Montreal has a death rate of 24 in one thousand, which equals New Orleans, which is put down at 24.8. The causes of this great infant mortality which annually swells the death rate of the city is put down to ignorance on the part of mothers in feeding their young; overcrowding is another cause; want of fresh air is another; noxious privy pits is another. These privy pits are gradually decreasing. In 1891 there were 8,523 of them in that city; now there are 5,201. Professor Adami considers that badly kept milk is also a strong factor and urges a purer milk supply.

The Annual Meeting of the Executive Health Officers' Association of Ontario was held at Brantford, Ont., on the 25th and 26th of June under the presidency of Dr. W. T. Connell, pathologist to Queen's University. Some very important papers on sanitary matters were presented to the meeting and the question of the control of smallpox received extended discussion. A "well-cleaning" day was advocated by one sanitary scientist, who said that there should be a day for cleaning out the well as for planting trees. He said that in the township of Waterloo this had been tried with great results, one effect being the lessening of typhoid fever. Another advanced scientist deprecated the habit of ladies kissing each other and one another, pointing out that it was a fruitful way of spreading disease. Another important matter was that of appointing a special Committee, one member from each county in the province, who will endeavor to have by-laws for the establishment of sanitarium submitted to the people. The following officers were elected: President, Dr. E. E. Kitchen, St. George; vice-president, Dr. Thomas MacFarlane, Ottawa; Executive Committee, Dr. F. G. E. Pearson, Brantford; Dr. Hoare, Walkerville; Dr. D. Dunton, Paris; Dr. John Herald, Kingston; and Dr. W. J. Arnott, Berlin; Secretary, Dr. P. H. Bryce, Toronto.

MISCELLANY.

No Yellow Fever in Havana.—There have been no cases and no deaths of yellow fever in Havana during the week ending June 17.

Plague in Formosa.—In his report to the Surgeon General

al, Stuart Eldridge, Acting Assistant Surgeon, U. S. Marine Hospital Service states that in Formosa the plague epidemic is showing no signs of abatement. He is unable to present consecutive statistics of the same, but, on May 23, the governor-general of that island reported the new cases and deaths from this cause, on May 21, to have been, respectively, at Tainan, 25 cases and 20 deaths, and at Taihoku, 16 cases and 9 deaths.

OBITUARY.

Dr. John Jury, at St. Louis, Mo., on June 13, aged 33 years—Dr. E. E. Walte, at New Bedford, Mass., on June 20, aged 43 years—Dr. Jeremiah L. Fordham, at Scranton, Pa., on June 28, aged 70 years—Dr. Joseph A. Galloupe, at Beverly, Mass., on June 24—Dr. Lewis M. Eastman, at Baltimore, Md., on June 27—Dr. John G. I. Whitehead, at Crosswicks, N. J., on June 29, aged 73 years—Dr. John W. Wilson, at Chatham, Va., on June 29, aged 75 years—Dr. Musgrove Stone, at East Radford, Va., on June 27, aged 70 years—Dr. W. L. Nichol, at Nashville, Tenn., on June 23 aged 73 years—Dr. G. H. Magness, at White Plains, N. Y., on June 25, age 50 years—Dr. Philip A. Taliaferro, at Tidewater, Va., on June 27—Dr. B. F. Hastings, at Whitman, Mass., on June 28, aged 65 years—Dr. F. L. Huston, at Sante Fe, N. M., on June 24—Dr. John G. Lumpkin, at Richmond, Va., on June 27, 71 years—Dr. Morris Tussell, at Chester Springs, Pa. June 29, aged 75 years—

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended June 29, 1901.

SMALLPOX—UNITED STATES.

Official List of the Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Hospital Service for the 7 Days Ended June 27, 1901.

C. E. BANKS, surgeon, granted leave of absence for 2 days—June 21, 1901.
HILL HASTINGS, assistant surgeon, to proceed to San Diego, Cal., for special temporary duty—June 24, 1901.
F. B. ADAMS, acting assistant surgeon, granted leave of absence for 3 days from June 23, 1901, on account of sickness—June 24, 1901.
C. W. BAILEY, acting assistant surgeon, granted leave of absence for 10 days from June 21—June 22, 1901.

Changes in the Medical Corps of the Navy, Week Ended June 29, 1901.

P. A. SURGEON E. M. SHIPP, detached from the Michigan and ordered to the Asiatic station via vessel sailing from San Francisco, July 15—June 24.
P. A. SURGEON W. B. GROVE, detached from the Naval Hospital, Norfolk, and ordered to the Michigan, June 28—June 24.
ASSISTANT SURGEON G. C. SMITH, detached from the Vermont and ordered to temporary duty on the Alvarado, July 1—June 24.
Vermont—June 24.
ASSISTANT SURGEON H. M. TOLFREE, ordered to the ASSISTANT SURGEON J. S. TAYLOR, detached from the Manila, and ordered to the Naval Hospital, Yokohama, Japan—June 25.
ASSISTANT SURGEON W. H. BUCHER, commissioned a passed assistant surgeon from April 15, 1901—June 25.
DOCTORS R. T. ATKINSON and A. W. BALCH, appointed assistant surgeons in the Navy from June 22, 1901—June 25.
P. A. SURGEON R. S. BLAKEMAN, ordered to the Naval Hospital, Norfolk, Va.—June 27.

GREAT BRITAIN.

Honorary Degree of L. L. D. Conferred.—The University of Glasgow recently conferred the honorary degree of L. L. D., upon the following foreign members of the medical profession: Prof. A. Barkan, San Francisco; Prof. W. G. Farlow, M. D., of Boston; Prof. Adolf Mayer, M. D., of Worcester, Mass.; Prof. Julius Wesner, University of Vienna; and Prof. Witkowske, of the University of Cracow.

The British Medical Association will meet at Cheltenham, Eng., July 30th to August 30th inclusive.

Hibernation of Anopheles in England.—Dr. G. H. F. Nuttall in reviewing the various observations that have been made as to the hibernation of the several species of anopheles in England, states that he himself had observed the larvae of *Anopheles bifurcatus* to hibernate, while larvae of *Anopheles maculipennis*, which were in the same tank, invariably died as the winter progressed.

CONTINENTAL EUROPE.

Russia's Anti-Alcohol Campaign.—It is now five years since the Russian Government assumed exclusive control of the manufacture and sale of alcoholic liquors. In nearly all the provinces the saloon has been supplanted by the government shops, in which a guaranteed pure article is sold in a limited quantity to each customer. None is sold to those already intoxicated. These shops are located quite a distance apart and no one is allowed to drink liquor on the premises where sold. The system is supplemented by officially appointed local committees in each large town, which are supplied with funds to establish attractive temperance restaurants, reading-rooms, and people's palaces. They are expected to maintain a general crusade against the use of alcohol. A portion of the enormous profits of the liquor monopoly is devoted to this purpose.—(*Carolina Med. Jour.*)

Physicians Suffer from Infection.—In a recent epidemic of typhus and typhoid fever in Elisavetgrad county (Russia) 7 out of 9 physicians became infected with one or the other of the diseases. Many nurses and medical students were among the victims. The epidemic was the outcome of a local famine.

Famine and Pellagra.—The famine, which is periodical in certain parts of Russia, is now affecting the usually fertile south. The peasants of the governments of Kherson and Bessarabia are forced to subsist exclusively on corn meal which is often spoiled by improper keeping. As a result of this diet the Italian leprosy became endemic, over 30 cases having been reported so far.

Results of the Pasteur Treatment in Russia.—At the Pasteur Station in the government of Samara 1108 persons were treated. The mortality was 0.09%. Including the cases which terminated fatally before the treatment was completed as well as one case of death from an unknown disease occurring after the treatment, a mortality of 0.47% is obtained. At the Station at St. Petersburg 587 persons were treated. Mortality 1.2%. Excluding the cases which terminated fatally during the treatment, the percentage is reduced to 0.5%.

Method for Administration of Chloroform.—Dr. Wohlgemuth, of Berlin has constructed an apparatus by which patients inhale chloroform mixed with oxygen. It has been tried by many prominent surgeons with excellent results. It is claimed that the apparatus obviates many of the disagreeable features that are caused during the administration of the anesthetic.

1.—By hepatic inadequacy Yeo means such defect or disturbance of the liver functions which, while stopping short of giving rise to what are known and generally accepted as diseases of the liver, leads to impairment of the general health. He includes in this category many, if not all, of those cases spoken of as irregular gout. He believes it is reasonable to infer either that these cases are improperly termed gout and should be termed instead cases of hepatic inadequacy or that hepatic inadequacy is the original cause of gout and that the manifestations of regular and articular gout are the near or remote results of the disturbance in metabolism thereby initiated. It has always appeared to the author that clinical evidence has been opposed to the conclusion that all or the greater part of the phenomena of gout as we now see them are the result of uratic precipitation in the tissues and that the widely spread and popular idea that the treatment of gout consists in the administration of so-called solvents of uric acid is an erroneous one. He has great doubt also whether uric acid has any other relation to gout than that its overproduction in the human body is a result of a gouty state, a state which he suggests takes its origin in disturbed hepatic metabolism. Although calomel does not really cause an increased formation of bile it acts on the bile expelling mechanism and promotes the flow of bile into the intestines, there to carry on the chemical and other changes in the intestinal contents which it is known to produce and it necessarily also promotes bile elimination. Calomel is used as extensively as ever in the treatment of functional disorders of the stomach and liver, in which the author includes many forms of irregular gout. He gives sodium bicarbonate and the other alkali in such cases because he believes that they promote the healthy function of the liver and that they favor metabolism generally. The method of their action, he believes, is by the promotion of osmosis. The remarkable effects of solutions of sodium salts in the hepatic functions is shown by their curative effect in gouty and dietetic glycosuria. They probably exert their remedial influence by a beneficial action on the gastric, intestinal and hepatic functions and on the nutritive changes in the tissues quite irrespective of any direct solvent action on sodium biurate. It is an undoubted fact that attacks of acute gout do occasionally occur while the patient is taking a course of sodium

waters, but certainly not frequently. The symptoms referable to hepatic inadequacy presented by patients with irregular gout are pale and often offensive feces, constipation alternating with more or less diarrhea, some enlargement of the liver with tenderness on pressure, muddy complexion, yellowish conjunctivae, sweetish bitter taste in the mouth, loss of appetite and high colored urine which is of high specific gravity and extremely acid and which has a color reaction that is adduced by adding nitric acid after boiling. The color produced under these circumstances resembles that of mahogany of various shades. The author does not believe that the kidneys are functionally diseased in these cases, but, on the other hand, is of the opinion that they are eliminating excrementitious substances that are normally excreted in the bile. There can be no doubt as to the intimate relation between the liver, the kidneys and the skin, the 3 great eliminating organs. We know that the liver is especially concerned in the metabolism of carbohydrates and of nitrogenous material. We know, also, that in gouty subjects the glycogenic function is frequently disturbed and that it is often restored by alkaline medication. It is not reasonable to conclude then that another function of the liver carried on coincidentally with the glycogenic function is also prone to be disturbed particularly since it is restored clinically by the same means. A third function of the liver is the formation of the bile; and in gouty subjects this is also frequently disturbed. Apart from individual peculiarities, which are common in gouty subjects, the safest diet for such patients is the simplest one that the individual capacity of the patient can dispose of. There is much in the quality and cooking of food and perhaps more than in the kind of food, and this also holds good as to the quality of wines. In the majority of instances the gouty patients that Yeo has seen have been extremely active and energetic people, and it is often difficult to get them to take sufficient rest. This excess of muscular activity constantly leads them to take an excess of food and then trouble arises because their excretory organs can hardly keep pace with the waste produced in the body. This is especially notable after middle age when the activities of the excreting organs become reduced and both liver and kidneys become inadequate. [J. M. S.]

2.—In the Croonian lectures on the chemical side of nervous activity, Halliburton first discusses the general composition of the nervous structures. The grey matter contains between 80% and 90% of water; the white matter contains 70% and the nerves contain from 61 to 65%. The solid materials of nervous tissues are very numerous. The most important and the most abundant and those of which we have the most accurate knowledge are the proteids and the phosphorized fats. In the grey matter the amount of protoid comprises over 50% of the solids. Nucleoproteid is the most abundant, while the other 2 proteids are globulins. One of these globulins, neuroglobulin coagulates at 47° C., and the other coagulates at 70° C. The phosphorized fat is known as protagon. On decomposition it yields lecithin and cerebrin. The cerebrins are nitrogenous glucosides; the sugar obtained from them having been identified as galactose. On hydrolysis lecithin yields not only fatty acid and glycerine but also phosphoric acid and cholin. The cerebrospinal fluid apparently plays the part of the lymph of the central nervous system. It is characterized by its low specific gravity, its clear watery character, its paucity in protoid and the presence in it of an unknown reducing substance which is not sugar. The importance of the cerebrospinal fluid from the pathological standpoint is that in it one would naturally look for the products of brain katabolism. The normal fluid, for example, contains the merest traces of cholin and proteids, but in pathological conditions in which the disintegrating side of metabolism preponderates over the assimilative, these materials, the chemical evidence of nervous breakdown, are much increased in quantity. The evidence is rather circumstantial than direct, that nervous material is,

during activity, in that state of unstable equilibrium which is designated by the terms metabolism. The signs of action that do exist are to be found chiefly at the beginnings and the ends of the fibres. These facts coincide with the arrangements of the vascular supply; the centers are richly supplied with bloodvessels but in a nerve these are comparatively insignificant. The necessity for an abundant supply of oxygen to the brain is seen from the rapidly fatal effects of cerebral anemia. The normal reaction of nervous tissue is alkaline, at death it becomes acid; but there is little or no evidence that acid is formed during activity. Experiments have shown that fatigue cannot be demonstrated in the splenic nerves. Evidence of fatigue products can be found in the central nervous system, however, by examining the cerebrospinal fluid. Chemical theories that explain sleep by the production of soporific substances, such as leukomains and reducing substances during waking hours depend upon the slenderest of evidence which will not stand rigid inquiry. It is within the bounds of possibility that the phenomenon of alternate periods of wakefulness and sleep may in the future be found explicable by the comparatively simple action of inorganic substances or their constituent equivalent. The monilliform enlargements seen on the dendrites are probably not the ordinary cause of loss of consciousness but merely secondary results of changes in the cell body. One should be very chary in concluding that the artificial sleep of a deeply narcotized animal is any criterion of what occurs during normal sleep. The sleep of anesthesia is a pathological condition due to the action of a poison; the drug reduces the chemico-vital activities of the cells and unconsciousness is in a sense dependent upon an increasing condition of exhaustion which may culminate in death. The sleep of health, on the other hand, is not produced by a poison; it is rather the normal manifestation of one stage in the rhythmical activity of the nerve cells, and though it may be preceded by fatigue and exhaustion it is accompanied by repair, the constructive side of metabolic action. [J. M. S.]

3.—Since the opening of the Royal Victoria Hospital, in 1894, 620 cases of typhoid fever have been treated, with a mortality of 5.4%. In fully 93% of the cases the onset was slow and was characterized mainly by frontal headache, *malaise* and loss of appetite. In 7% the onset was sudden and closely resembled that of pneumonia or pleurisy. In 5 or 6 cases the onset was characterized by symptoms similar to those of a sharp attack of appendicitis. In about 10% of cases repeated rigors and chills were reported during the first week of the illness. Epistaxis was an early symptom in about 12% of the cases. Decided symptoms of meningitis were found in less than 0.5% of the cases. Perforation and hemorrhage combined caused 58.8% of the deaths while all others causes combined caused 41.2%. In the 11 cases of perforation which occurred out of the 620 cases reported, operation was attempted in 8 only, but in no instance with a successful result. Operation for typhoid perforation should, if possible, be performed within 12 hours of the accident. The practical difficulty, however, is the recognition of the perforation. Hemorrhage of a decided character occurred in 5.48% and was the cause of death in 26.4% of the fatal cases. Opinion is strongly indicated in the treatment of intestinal hemorrhage, but the reaction following its continuous use in large doses for several days may be very considerable. There were 7 cases of cholecystitis, all of which recovered except one. Relapse occurred in about 9% of the cases. Serum diagnosis was attempted in 370 cases, with a positive result in all but 8. Out of 96 cases in which the reaction was looked for on the day of discharge from the hospital, it was found positive in all but 6. There was one case of typhoid without intestinal lesions. The routine treatment was hydrotherapy, except in a few cases in which contraindications existed. [J. M. S.]

4.—T. J. MacLagan discusses the treatment of typhoid fever recommending to the general practitioner the great

necessity of consultation of the surgeon in case of typhoid fever, showing symptoms indicative of perforation, and calls attention to the good results that have followed the surgical treatment of perforation. The author recommends a new form of treatment for overdistension of the colon accompanied by small fetid stools. It is claimed that when these symptoms are present, the cecum contains a quantity of fetid sloughs which have come from the small intestines. When this condition is present, respiration is greatly embarrassed from the distended colon and the patient is suffering from septic absorption. Under these circumstances it is recommended that the cecum be opened and drained. [J. H. G.]

5.—Buchan reports the case of a boy, aged 11 years, who was suffering from typhoid fever. On admission the patient complained of pain, which was increased on pressure and movement, in the left elbow joint, but no distinct areas of tenderness could be made out. Four days after admission the joint became distinctly swollen. After aspiration 1½ drachms of clear, serous fluid were withdrawn which proved sterile on bacteriological examination. After that the temperature fell to normal. Later, however, the pain was again felt and the swelling reappeared. A second aspiration resulted in the removal of a purulent fluid which contained a large number of streptococci and staphylococci. Careful search was made for the bacillus typhosus and the bacillus coli communis, but neither were found. The joint was freely incised and washed out with 1 to 80 carbolic solution. The patient was cured and the movement in the joint was almost entirely restored. The author considers the case to be one of true typhoid arthritis. [J. M. S.]

6.—In typhoid fever there is a great increase in the bacterial fermentation of the intestinal contents. In the anemia which occurs in a fair proportion of typhoid fever we have an opportunity of investigating the relation between bacterial fermentation with absorption of toxin and the modifications that occur in the blood. Houston gives the history of a patient who suffered from a protracted attack of typhoid fever from the bowels and which was taxis and hemorrhage from the bowels and which was prolonged by phlebitis and abscesses about the anus and in the axilla. During his illness the patient became quite anemic. In the early stage of the disease the blood was practically normal except that the white cells were somewhat diminished in number and the large mononuclear leukocytes were slightly increased. In the second stage, that of commencing anemia with no inflammatory complications, the hemoglobin and the red bloodcorpuscles were considerably diminished, and the lymphocytes and the mononuclear leukocytes were increased in percentage. In the third stage, that of anemia persisting with phlebitis, the hemoglobin was somewhat lower in percentage, the leukocytes had increased in number and the percentage of polymorphonuclear cells had considerably increased. In the fourth stage, that of increasing anemia and diminishing phlebitis the hemoglobin was still lower in percentage and the leukocytes had again diminished in number. The percentage of polymorphonuclear leukocytes had fallen and that of the lymphocytes had risen. In the fifth stage, in which the patient was profoundly anemic and in which abscess formation was present, the percentage of hemoglobin had reached its lowest point. The blood was of decidedly chlorotic type. The number of white cells was somewhat higher and the differential count showed a greatly increased proportion of polymorphonuclear leukocytes. In the sixth stage, in which the patient was convalescent with subsiding inflammatory symptoms, the blood resembled very closely that of the second stage already referred to. In this case the toxins of the typhoid bacillus had no hemolytic power and the loss of hemoglobin per cmm. was merely the effect of an increase in the plasma. The anemia of typhoid fever tends to become of the chlorotic type. The leukocytes are always below the normal and present a

gradual decrease unless inflammatory complications occur. Although there is no very great increase in the number of leukocytes during the existence of an inflammatory complication, the differential count is very materially altered. This peculiarity of the blood of typhoid fever seems best explained by the hypothesis that the anemia is the result of dilution of the blood with excess of plasma. Taking this into consideration, it seems evident that the leukocytes in typhoid fever react normally to inflammatory toxins, but that this reaction is masked to a large extent by the dilution of the blood. Leaving out the inflammatory periods and allowing for the dilution, we find that the absolute number of polymorphonuclear leukocytes remains, roughly speaking, stationary throughout. The lymphocytes, if we take into account the dilution of the blood, have increased in absolute numbers almost identically in proportion to the dilution. The mononuclear leukocytes show considerable increase. The view of Ehrlich that the apparent decrease in the polymorphonuclear leukocytes in typhoid fever is due to negative chemotaxis is not confirmed by this study. The tendency to dilution of the blood in typhoid fever may be due to the increased activity of the lymphatic apparatus of the alimentary canal. [J. M. S.]

7.—In South Africa, Porter has met with a variety of continued fever which is not malarial and not enteric. It is rather sudden in its onset and the temperature may be from 102° to 104° at the end of the first day. There is usually a good deal of headache and considerable disturbance of the gastrointestinal tract. There is more often constipation than diarrhea. There is very considerable difficulty in being certain that the case is not one of enteric fever. The disease lasts from 2 to 8 days, and there is very rapid convalescence. [J. M. S.]

8.—From a study of the Pasteur-Chamberland and Berkefeld filters Horrocks concludes: (1) That typhoid bacilli are not able to grow through walls of a Pasteur-Chamberland candle, and if proper care is taken to prevent the direct passage of the bacilli through flaws in the material or imperfections in the fittings, the Pasteur-Chamberland filter ought to give complete protection from water-borne enteric fever. (2) That typhoid bacilli can grow through the walls of Berkefeld candles, probably owing to the large size of the lacunar spaces and the consequently diminished immobilizing and devitalizing influences. The time required for the typhoid bacilli to traverse a candle varies between 4 and 11 days, and appears to be largely dependent upon the nutriment supplied to the organisms by the medium in which they exist. In order to obtain complete protection from water-borne enteric fever when employing Berkefeld filters it is necessary to sterilize the candles in boiling water every third day. [J. M. S.]

9.—Brown reports two cases of hematuria which followed the use of 10 grains of urotropin 3 times a day, for 8 days. The symptom rapidly disappeared after the drug was stopped. The bladder seems to have been the source of the hemorrhage. [J. M. S.]

10.—Waldo reports the case of a man, aged 33 years, who was suffering from dyspepsia and giddiness. He fancied he could not sleep, and so had been in the habit of taking different kinds of hypnotics, principally sulphonal. A few days later he developed gastritis and his urine resembled Port wine in appearance. It contained neither albumin nor blood, but the spectroscope showed bands corresponding to those produced by hematophorphyria. The patient died. [J. M. S.]

12.—Hewlett and Murray find that the Klebs-Loeffler bacilli and the pseudo-diphtheria bacillus exist in the throats of a large number of cases, especially in children, without producing recognizable symptoms. Out of 385 children under the age of 14, who were admitted to the Victoria Hospital for children for some illness other than diphtheria, the pseudo-diphtheria bacilli were found in 24% and the Klebs-Loeffler bacilli in 15%. They believe that

the presence of children under 2 years of age in a hospital ward increases the risk of outbreaks of diphtheria. It is clear that babies and young children are not the harmless and innocent creatures usually imagined and that kissing and other similar artificial demonstrations of childish affection should be discouraged. It is, moreover, more important and perhaps more practicable that mouth cleaning in infants and teeth cleaning in young children should be insisted upon more vigorously. [J. M. S.]

2.—Lamb and Hanna write upon the standardization of Calmette's anti-venomous serum with pure cobra venom. These authors state that Calmette employed for the purpose of immunization and standardization, a venom composed of a mixture of colubrine and viperine poisons, which is heated to about 73° C. for one half hour and filtered. The authors review the methods employed by Meyers and Martin, and finally they give a report of a series of experiments upon methods of standardization. In conclusion they emphasize that the dose of fresh serum in every case of cobra bite poisoning should be from 30 to 35 cc. If symptoms set in before the treatment is instituted a larger dose should be given. After a series of experiments they also conclude that anti-venomous serum undergoes deterioration in hot climates. The higher the mean temperature the more rapid is the deterioration. [F. J. K.]

3.—Kirtan contends that feeding is of great importance in the treatment of diphtheria. He considers the various methods of feeding: (1) feeding by the mouth; (2), the nasal tube; (3) the rectum, and (4) subcutaneous injections. He contends that feeding should be performed by the mouth in all cases when practicable. The contraindications to mouth feeding are the following: Great pain produced by faucial swelling; vomiting; food gaining entrance into the larynx by coughing; exhaustion produced by mouth feeding owing to struggling of the patient; continued vomiting. The author states that nasal feeding is indicated when there is an inability to swallow from irritation or when due to a paralysis of the muscles of deglutition, etc.; when feeding by the mouth produces coughing or vomiting, or in cases which are exhausted by mouth feeding, and in some cases the moral effect of nasal feeding induces the patient to take food by the mouth. Rectal feeding is indicated when there is vomiting, difficulty in passing the nasal tube or when nasal feeding induces struggling, fright or epistaxis. The author believes that subcutaneous injections of horse serum are beneficial. In the author's practice he frequently combines the various modes of feeding. This article is concluded with a report of four cases, special reference being made to feeding. [F. J. K.]

4.—Pike reports a case of scarlet fever which occurred in a girl aged 14, in 1898. The patient was isolated together with one of her sisters. After a prolonged illness the patient made a good recovery. The author first saw the patient on October 14th, 1899, when she complained of carache. Upon examination he found that there was a discharge from the meatus, and there was some swelling over the mastoid.

On October 18th an older sister developed scarlet fever. This infection occurred apparently without any outside infection. The patient was operated upon for mastoid necrosis, and after a severe and prolonged illness made a good recovery. During her illness she had an attack of nephritis. The author emphasizes that this case illustrates the following: An inquiry whether the infecting principle of scarlet fever was latent in the middle ear and mastoid cells. [F. J. K.]

5.—Harper maintains that urea is a constructor or builder up when administered in tuberculosis. He has reached this conclusion after studying a number of cases which improved after being treated with urea, and dieting on foods rich in urea—kidney, liver or brain. He further mentions that a few chronic phthisical patients have stated that food rich in urea acted like a stimulant on them. The author contends that there is an antagonism between gout and its allied diseases and tuberculosis. He gives a report of five cases of tuberculosis which were treated with urea in conjunction with other well-recognized modes of treatment. All of these cases improved. [F. J. K.]

6.—Richmond recommends sulphur in the treatment of dysentery, and believes that this drug is a very valuable addition to our stock of remedies for this most distressing complaint. He states that sulphur seems to possess a strong antiseptic action, and induces healing of any ulcerated surfaces of the intestines. [F. J. K.]

7.—Gordon read a paper before the Devon and Exeter Medico-Chirurgical Society on May 17th, 1901, on "the practical choice of climate in phthisis." He divides the cases into two classes. (1) Patients who are to be kept at home; (2) patients who are to be sent away. The author concludes that there are definite indications for the choice of foreign climates (climates for the few). There are no such definite indications, however, for the choice of home climates, and he contends that while sanatoria are of great value, they do not supersede climates, and that the beneficial effects of the English sanatoria depend largely upon their location. [F. J. K.]

8.—A. Christy Wilson reports four cases of gastric and duodenal perforation. The first was a man 28 years of age who was admitted with all the symptoms of an acute general peritonitis. Operation was done four hours after the onset of the symptoms. Perforation was found in the anterior wall of the stomach $\frac{1}{2}$ inch from the pylorus. The ulcer was inverted by two rows of sutures and then a fold of omentum was stitched over it. As the contents of the stomach had found their way to every part of the cavity a second incision was made above the pubes and thorough irrigation done. The patient made an excellent recovery. Case No. 2 was a man aged 21. Symptoms started with a sharp pain in the stomach which was relieved by laudanum. At the time of admission the patient would not consent to operation, which had to be postponed until 92 hours after the onset of symptoms. In this case the contents of the stomach had escaped through the perforation, but had been well walled off by adhesions. This patient recovered. Case No. 5 was a man aged 22. Operation five hours after onset of acute symptoms. A second low incision was also made here after the ulcer had been closed for the purpose of cleansing the pelvic cavity. This patient also recovered. Case No. 4 was a man aged 48 years who suddenly developed symptoms of peritonitis. Operation was done 28 hours after the onset. Perforation was found in the anterior wall of the duodenum. After thorough irrigation this patient made a slow but satisfactory recovery. The cases are interesting because they all occurred in men. The author strongly advises a second low incision in cases requiring thorough abdominal and pelvic cavities, as hernia is much less likely to follow two incisions than a single long one. [J. H. G.]

9.—Jardine believes that we have made some little advance in our knowledge of puerperal eclampsia within recent years. It is now generally admitted that the fits are caused by the action of the toxin which has accumulated in the system of the mother. Some observers have maintained that micro-organisms are the prime factor, but of this no sufficient proof has been advanced. He disputes the statement of the disappearance of the albumen in the urine on the death of the fetus; he has seen three cases of eclampsia and one of severe albuminuria with macerated fetuses and in all the albumen was abundant. Jardine especially favors the action of saline infusions in the treatment of this

disease. The infusions are given under the breast or into the abdominal wall. His experience is leading him to stop the use of antispasmodics. In addition to the infusions he employs various drugs to meet the varying conditions. He reports four examinations of the liver from fatal cases of eclampsia. In each instance the liver-cells showed especial degenerative changes, thus carrying out the statement that this organ is at fault in this disease.

3. Chronic Gonorrhea and Postgonorrheal Urethritis.—A Sketch of their Modern Treatment. FERD. C. VALENTINE.
4. Tuberculous Mastitis. R. A. GIULIANA.

2.—Prof. Schott, of Bad Nauheim, discusses tonometric examination in chronic disease of the heart. The difference in the results obtained by various practitioners who have used the Schott treatment, in that they have observed a decrease in the blood pressure instead of its increase which the brothers Schott have claimed for the treatment, is explained. The Schott brothers believe that this difference in the results has been due mainly to the inaccurate instruments hitherto applied to the body, which in consequence gave varying results. Schott says that the profession has great reason to be gratified with the invention by Gaertner of his tonometer, an instrument which enables us to read directly blood pressure at the time of examination. The paper is mainly taken up with a report of the results of tonometric examinations made with this instrument at Bad Nauheim during the past two years. [T. L. C.]

3.—F. C. Valentine discusses the chronic forms of gonorrhea, and describes their modern treatment. The article goes carefully into these conditions and deals minutely with the treatment. His article is illustrated by cuts of a number of instruments, including his own urethroscope. [J. H. G.]

NEW YORK MEDICAL JOURNAL.

5. The Mental Diseases of Childhood. WILLIAM B. NOYES.

2.—A. Ravogli, in Notes on Ringworm, gives M. Sabouraud's conclusion: Under the name of tinea tonsurans trichophytina, have been confounded two diseases, which, although they have some similarity of appearance, yet are different on account of the different parasite from which they are derived. According to Sabouraud, one kind of affection is the result of a parasite which was discovered by Gruby over fifty years ago and named Microsporon Audouini. This causes the kind of ringworm most contagious and most refractory to treatment, which is often seen in the schools of France. The microscopical characteristics are the smallness of the spores of the parasite, and the clinical are that it is limited to children and attacks the scalp only. The other disease is caused by the real trichophyton, which shows large spores. Sabouraud divided them into two groups, according to the location of their spores inside or outside of the hair, calling the first endothrix, and the second ectothrix. The former attack principally the scalp, and only at times the hairless parts, tinea circinata; the latter attack the skin, occasionally the scalp in children and are nearly the sole cause of ringworm of the beard. The endothrix is spread from man to man; the ectothrix is the result of a direct inoculation from animals, such as the horse, the cat, etc. Of both these

varieties of large spored fungus there are numerous species, and Sabouraud explains the polymorphism of ring-worm by the multiplicity of the species. They have one objective characteristic in common, namely, the circinate outline of the epidermic lesions. [T. M. T.]

MEDICAL NEWS.

June 29, 1901. (Vol. LXXVIII, No. 26).

1. The Importance of Recognition of the Significance of Early Tuberculosis in Its Relation to Treatment. E. L. TRUDEAU.
2. A Study of Some Complications and Sequelae of Typhoid Fever. H. A. HARE and H. R. M. LANDIS.
3. Treatment of Diabetes Mellitus. ABRAHAM MAYER.
4. Cutaneous Manifestations in Diabetes. S. SHERWELL.
5. Diabetes in Surgery. ROBERT T. MORRIS.

1.—E. L. Trudeau says that persistent slight cough, with loss of flesh and strength, slight afternoon rises of temperature and constant lassitude, are the symptoms which even without physical signs point in many cases to incipient tuberculosis. These are too often disregarded on account of the patient's desiring to stay at home as long as possible. This and the disinclination of the physician to alarm him, explain in a great measure the waiting policy which is so often adopted and which generally proves fatal.

[T. M. T.]

3.—A. Mayer, in his article on treatment of Diabetes, gives the following complications: Diarrhea, tendency to suppurative, phthisis, gangrene and coma. As diarrhea frequently follows a constipation, the latter condition must be avoided. This diarrhea must be treated by a mixed diet, opium, iron and washing out of the intestines. The tendency to suppurative is met by diminution of the hyperglycemia and glycosuria and antiseptic local medication. Phthisis is very common, causing death in about 25% of the cases. If a case should have phthisis, a change to a milder climate, and large quantities of fatty foods, with some alcohol, must be given. In gangrene the dietetic treatment must be enforced and the gangrenous parts treated with dry dressings and according to modern surgical principles.

[T. M. T.]

4.—S. Sherwell gives the following order of the cutaneous manifestations in diabetes: (1) Generalized xeroderma, which is quite common; (2) Eczematous dermatic manifestations occurring in any region of the skin, especially prone to attack the flexor surfaces, and more especially the genital, anal and inguinal regions; (3) Furuncular and carbuncular manifestations are quite frequent in this condition, and are found generally in the nuchal and gluteal regions; (4) Erythematous lesions, some evanescent, others of the graver kind, as erysipelas, are commonly present; (5) Gangrene; (6) Dermatitis herpetiformis of Duhring; (7) Xanthoma diabetorum; (8) Blastomycotic dermatitis. The last two are the only tumor formations found in this disease. [T. M. T.]

5.—R. T. Morris gives the three principal reasons why diabetes interferes with the surgeon: (1) The sugar circulation in the blood is hygroscopic and it draws water from all the tissues of the body until the tissues are actually too dry. This must interfere with the normal process of repair, and it probably does so in several different ways; (2) The surgeon must give these cases special attention because the fluids of a wound loaded with sugar are, in all probability, excellent culture media and particularly susceptible to the attacks of bacteria. Rigid asepsis is, therefore, demanded; (3) certain anesthetics may precipitate an impending nephritis because of the unusual labor involved in excreting sugar. In these cases the author uses nitrous oxide and oxygen instead of the other anesthetics, especially avoiding the use of ether. [T. M. T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

June 27, 1901.

1. A Study of the Food Consumed and Digested by Four Members of the Harvard University Boat Crew in June 1900. W. O. ATWATER and F. G. BENE-DICT.
 2. Some Forms of Intestinal Obstruction due to Adhesions. A. T. CABOT.
 3. Catharsis in Abdominal Surgery. L. R. G. CRANDON.
1. Atwater and Benedict conclude their paper on the

study of the food consumed and digested by four members of the Harvard University Boat Crew in June, 1900. The results of the digestion experiments are given in tables. The amount of food eaten by the four men collectively was weighed each day, no attempt being made to learn how much each individual man ate. The amounts of feces excreted by each individual during the whole 7 days were weighed, so that the amounts for each were determined separately. It was found, according to the figures of the table, that 92.5% of the nitrogen, and 92.2% of the protein of the food are available to the body. The diet of the athletes furnished on the average 154 grams of protein and had a fuel value of 3,925 calories, while in the diet of men in an ordinary occupation the protein would not have averaged much over 100 grams, or the fuel value much over 3,300 calories per man per day. The amount and composition of the urine was carefully determined, and the results are tabulated. The nitrogen balance was also determined. These experiments bring out the apparent usefulness of sugar as a supplementary food for men subject to intense muscular strain. A notable feature of the experiments was found in the fact that the nitrogen excreted by the kidneys and intestine was considerably less in amount than the total nitrogen of the food. This means that there was considerable storage of nitrogen in the body. [T. L. C.]

2.—A. T. Cabot describes some forms of intestinal obstruction due to adhesion. Reference is first made to adhesions forming about the stomach and duodenum, such as result from inflammation of the gall bladder and its ducts. Particular attention is paid to chronic obstruction of the intestine such as occurs when this viscus has been overloaded. The seat of the trouble is usually in the ileum or the sigmoid flexure. The author thinks that these portions of the alimentary tract, because of their fixed position, are more liable to become constricted after inflammation about them, because they are unable to adapt themselves to new positions. Appendicitis is a frequent cause of chronic obstruction of the ileum. It is shown that separation of the adhesions and restoration of the ileum to its normal position is not sufficient to relieve the condition. The sigmoid sometimes is attached by a long, loose mesentery which allows it to sag down into the pelvis, and here become kinked by inflammatory adhesions. Cabot has met with 3 such cases in the past 18 months, each of which is briefly reported. The article is illustrated by a number of cuts. [J. H. G.]

3.—Crandon gives the results of observations made during his service as house officer at the Boston City Hospital on the use of catharsis in abdominal surgery. It has been proved by a number of studies in normal intestine and by use of purgatives that peristalsis is almost entirely reflex action. The lower half of the ileum has been determined to be the part where the intestinal contents move fastest. It has been found that the vagus nerve when stimulated reflexly or directly increases peristalsis, and that moderate stimulation of the splanchnic nerve decreases it. Any decrease in the normal activity of the nerves and nerve-centres must result in constipation. The most important conditions under which peristalsis may take place along the small intestines are a relatively healthy condition of the whole thickness of the intestinal wall, and the integrity of the reflex arc. His studies cover a hundred and seventy-nine abdominal or pelvic cases. Of these 148 were cases of peritoneal and pelvic inflammation and ovarian cysts, 8 tuberculosis, 2 malignant disease, and 21 cases of mechanical obstruction. The conclusions which he presents are: (1) In acute pelvic peritonitis both enemata and drug by mouth should be used to produce catharsis before operation; drugs by mouth and oil enemata after operation. (2) In all acute inflammatory conditions of the abdomen in which the alimentary tract is involved, the bowels should be moved by enemata alone, before and after operation, the enema of salts, turpentine and glycerin being the best. [W. A. N. D.]

AMERICAN MEDICINE.

June 22, 1901.

1. The Treatment of Abdominal Aortic Aneurysm by a Preliminary Exploratory Celiotomy and Peritoneal Exclusion of the Sac, Etc. RUDOLPH MATAS.
2. Persistence of the Thyroglossal Duct. DAVID RIESMAN.
3. Myomectomy of Nine Myomas During Pregnancy and Delivery at Term. JOHN DUNCAN EMMETT.

4. Subtrochanteric Osteotomy for the Deformity Following Hip Disease. E. H. BRADFORD.
5. The Hallucination of Digitals, Etc. HARRY ORVILLE HALL.
6. The Treatment of Congenital Dislocations of the Hip-joint. LEONARD W. ELY.
7. Prevention of Disease Infection by Micro-organisms Through the Mouth and Nasal Cavities. ROBERT REYBURN.

1.—Rudolf Matas discusses the treatment of **abdominal aortic aneurysms** by a preliminary exploratory celiotomy and peritoneal exclusion of the sac followed later by wiring and electrolysis with a report of two hitherto unpublished cases. The first case is one of the author's in which an aneurism involving the upper celiac region in a young man, 22 years of age, was treated by various methods without success, the Moore-Corradi method was determined on. The patient's abdomen was opened and it was discovered that the aneurysm presented above the stomach, pushing above it the pancreas which was in immediate contact with the abdominal wall. The splenic vein and artery were stretched over the pancreas, which fact would have made puncture without opening the abdomen a most serious undertaking. The stomach was greatly displaced downwards. The viscera were displaced from over the aneurysm, and sutured to the parietal peritoneum and sutured in such a manner as to leave exposed an area of the aneurysmal wall about the size of a silver dollar. Excepting over this area the abdominal wound was closed and a portion over the aneurysm allowed to heal by granulation. About a week after the operation 12 ounces of sterile gelatine in normal salt solution 10% was injected under the skin. This was followed by a great deal of pain, a rise of temperature to 105° F. These symptoms gradually subsided. One month subsequent to the operation no improvement was noted. In reality the patient was growing worse and suffering more pain. At this time under Schleich's anesthesia needling of the wall of the aneurysm was done. No improvement followed this. It was then determined that the Moore-Corradi treatment should be instituted. Ten feet of drawn silver wire were introduced through an insulated cannula and electrolysis was employed for four hours and twenty minutes. Milliampères varied from 80 to 200. The patient complained of very little pain at any time during the electrolysis. The impression made by the treatment upon the aneurysm was quite marked. Improvement, however, was only transitory, and the patient gradually failed, dying 19 days after the introduction of the wire. During the latter days of his life he suffered a great deal of pain. No postmortem examination was allowed, but through a small abdominal incision it was found that a diverticulum had developed, making a new aneurysmal sac, which had ruptured, producing death. Out of 15 cases of abdominal aneurysm treated by the introduction of wire and electrolysis 3 have been cured. Attention is called to the long electrolysis in this case, and the high milliamperage of the current. In the original aneurysmal sac this treatment had caused an organized clot to form. The author thinks that there is a distinct advantage in a preliminary celiotomy, such as he did in this case. The technique of the operation is then discussed in detail. The statistics of the operation are next gone into. The author thinks that there is only a small percentage of abdominal aortic aneurysm which is to be treated by this method, and that it is a mistake to apply it indiscriminately in this condition.

[J. H. G.]

June 29, 1901.

1.—Matas concludes his discussion of the treatment of **abdominal aortic aneurysm** with a consideration of the applicability of the Moore-Corradi method. It is shown that the cure of the aneurysm, should this be situated in the first or second portion of the abdominal aorta, as is usually the case, may result in obstruction of the circulation through the splenic, renal, mesenteric, or other vessels, and consequent gangrene of the tissues supplied by these. A number of cases are then recited in which it is shown that these results have followed the cure of the aneurysm. It is shown very conclusively that the dangers of this treatment excepting in the last division of the abdominal aorta are very great. The great difficulty lies in the fact that a determination of the situation of the aneurysm even when

a celiotomy is done, is very great. The objections to the method are summarized as follows:

1. The cure of the aneurysm may lead to the death of the patient by obliterating the orifice of important visceral arteries; this is most likely to occur in dealing with aneurysms of the upper or celiac division of the abdominal aortic tract—i. e., in about 50% of the cases.
2. Secondary rupture of the sac from the strain put upon weak portions of the sac in multilocular aneurysms, after partial coagulation of the contents has taken place (particularly likely to occur in subjects of general endarteritis with atheroma.)
3. Escape of wire through a large aneurysmal orifice into the lumen of the aorta, with migration upward into the heart leading to perforation, traumatic endarteritis, endocarditis, with the formation of secondary thrombi and emboli.
4. Danger of perforating the sac by stiff wire or by overcrowding the sac with too much wire.
5. Danger of extension of clot from the coagulum in the aneurysm to the main artery, leading to fatal blockade at the bifurcation, with gangrene of the lower extremities.
6. Danger of rupture of sac from sudden withdrawal of abdominal support and displacement of adherent organs in the course of the exploratory laparotomy.
7. Danger of mistaking a fusiform for a sacciform aneurysm.
8. Danger from emboli and thrombi following incomplete coagulation of the blood in the sac (a very rare and practically unknown occurrence in abdominal cases).
9. Danger of shock.
10. Danger of sepsis.

2.—David Riesman reports a case of **persistence of the thyroglossal duct**. The patient was a man of 56 years, who was injured 38 years ago, while in play. He struck the front of the neck against another boy's knee. There has been more or less constant discharge of a thin or sometimes whitest fluid, occasionally thick, from what appears to be a moist dimple in the median line of the neck. This is the second case of the kind which Riesman has seen. He believes that the traumatism was only an incidental cause of the fistula and a blind tract of congenital origin existed, the distal end of which was near the surface of the skin. The blow merely served to remove the slender partition walls which separated this tract from the interior. As to treatment it is evident that only a complete extirpation of the canal with its epithelial lining can bring about a permanent cure. [T. L. C.]

3.—Emmet remarks, in speaking of **myomectomy during pregnancy**, that Gutiérrez, as quoted by Delagènière, maintains that of 295 myomatous women 51 become pregnant. If these statistics are accurate it would represent the proportion of about 17 pregnancies in every 100 cases of myomata. Durkee, quoted by Howard Kelly, makes this proportion only 2.03%. Fortunately no such proportion even as this later one presents practical difficulties to the gynecologist or obstetrician, for it is an established fact that many myomatous uteri carry their pregnancies to term and through delivery. The myomata in these cases are either pedunculated at the time of conception or become so at pregnancy, as a rule, but a number of cases are on record of subperitoneal sessile tumors in or near the fundus, which have presented no serious difficulty at term. All authorities give the following general rules regarding indications of the various forms of this condition: Small myomata and those situated at or about the fundus, or even lower in the body of the uterus frequently do not interfere with normal pregnancy and delivery if these tumors are pedunculated. Sessile tumors are likely to cause abortions, but if situated at or near the fundus they need not do so. When myomata are situated at or near the uterus or cervix or in the lower third, myomectomy is justifiable and indicated because these tumors will probably interfere with the descent of the uterus into the pelvis and present a serious obstacle to delivery. These data divide myomata of the pregnant uterus into three classes, both in regard to prognosis and in regard to indications. Turner, of Paris, gives the following statistics of myomectomy during pregnancy: Between the years 1874 and 1890, 33 of these operations were reported with 61% fetal mortality and 36% of maternal mortality, but between the years 1890 and 1900, the reported operations are 44 with only 21% of fetal mortality and 9% of maternal

mortality. Emmet records a successful case of this operation. [W. A. N. D.]

4.—E. H. Bradford describes the various methods of performing subtrochanteric osteotomy for deformity following hip-joint disease. The author calls attention first, to the great inconvenience and mortification which accompany these deformities, and endeavors to impress upon the profession the good results which are obtained from osteotomy and correction. Transverse osteotomy will be found satisfactory in cases of flexion without adduction. The division of the bone should here be done at or below the position of the lesser trochanter, the bone being divided from 1 to $\frac{3}{4}$ of its thickness, the remaining portion being fractured by adduction and flexion, though of course the corrector of the deformity must be by the reverse of these motions. Oblique osteotomy is indicated when increase in the length of the limb is much desired. Wedge-shaped resection of the femur has no practical advantage over oblique osteotomy. The success of all these methods depends largely upon the after treatment. It is often-times difficult to put the limb in the desired position and at the same time keep the fragments in apposition. Union, however, after this operation even when the fragments are not in line, is very good and firm. When there is rigidity of the lumbar spinal column it is well to fix the limb in a slightly flexed position, as otherwise with the stiff spine the patient will have discomfort in a sitting position. In older patients, too, slight flexion, not more than 15° is to be employed. The author employs plaster of Paris usually in fixing the limb after operation. Traction, however, by the ordinary weight and pulleys, is to be employed where complete correction is not possible, and it is desirable to stretch the contraction of the soft parts. The patient should not bear weight for ten weeks after the operation. Crutches, however, may be used at the expiration of eight weeks. The operation should not be done on too young or rapidly growing children. Not infrequently severe knock-knee accompanies the hip deformity and requires osteotomy subsequently. The author thinks the operation satisfactory to both patient and surgeon. [J. H. G.]

6.—L. W. Eli discusses the treatment of congenital dislocation of the hip and describes three methods of treatment, first, the closed method, where no incision is made, second, incision in splitting of the capsule and reposition of the head is made; third, the open method with deepening of the acetabulum. The first method of treatment is applicable in children under 10 years of age. The author thinks that the want of success which not infrequently follows this method is due to the fact that it is not carefully carried out by the operator, and that many surgeons approach the condition half-heartedly. The various methods of carrying out the treatment of congenital luxation are carefully outlined by the author. [J. H. G.]

5.—Harry Orville Hall contributes a paper on the hallucinations produced by digitalis. He was lead to this study of the subject in the observing throughout the course of a patient's illness, a delirium which seemed inexplicable. This patient had been taking digitalis prior to an onset of the nervous disturbances. Hall has made an abstract of Dr. Durvlez's paper in which 20 cases were reported in which delirium followed the administration of digitalis. Hall believes the subject one that is worthy of more extended observation. [T. L. C.]

7.—Robert Reyburn discusses the prevention of disease infection by microorganisms through the mouth and nasal cavities. He calls attention to the oft repeated necessity of preserving and maintaining the health of children by good hygiene, and keeping their mouths and nasal cavities healthy and antiseptic, and mentions many common diseased conditions due to infection through the mouth and nasal cavities. [T. L. C.]

2.—Ransom determined definitely the hemolytic effect of saponin on dog's blood and found that the minimal dose which destroyed the corpuscles was 2 mg. in 0.7 cc. of blood. The same amount of saponin would cause some destruction in 0.9 cc., but in 1.5 cc. there was but a slight effect, and in 2 cc. no effect. He found that if the corpuscles were centrifugated saponin was much more active than when whole blood was used. It acted in a dilution of 1 to 200,000 in this case, while with the whole blood it did not act in a dilution of 1 to 40,000. A similar result has been seen in the use of eel serum. Different kinds of blood showed different susceptibilities evidently owing to the presence of different amounts of immune bodies. He found that 0.75 cc. of serum was sufficient to fix 2 mm. of saponin, and that this power of fixation was not lost after heating for half an hour at 55° C. He also found that the red corpuscles themselves fixed saponin. After laking with distilled water and centrifugating the stromata of the red cells, he determined that the stromata themselves fixed saponin. Shaking dog's serum with ether, and driving off the remaining ether left the serum in a condition in which it could not fix saponin, while the ethereal extract had the power of fixation. Investigation of the ethereal extract showed that its chief component was cholesterol, hence he took cholesterol, dissolved it, and found that this solution had active power of fixation of saponin; lecithin had no such influence. A mixture of cholesterol and saponin had no hemolytic effect upon various kinds of blood if the amount of cholesterol used was sufficiently large. He refers to the fact that Phisalix has demonstrated a similarly immunizing effect of cholesterol toward snake poisoning. The cholesterol in the serum, therefore, acts in excreting the poison, but, by combining with the poison, the cholesterol in the red blood corpuscles is active in the production of the poisonous effects; that is, the saponin acts upon the red corpuscles by acting in combination with the important part of the structure, the cholesterol. The action is somewhat slow, however, and there is apparently an incubation period because saponin first acts upon the surface of the red corpuscles, and unless this action is very severe no hemoglobin escapes. So far as has been determined by Ransom cholesterol is active only toward saponin and the members of the saponin group, but not toward other vegetable hemolysis or toward foreign sera. [D. L. E.]

3.—Fraenckel mentions one case of death as a result of complication of typhoid fever with diphtheria. The temperature of the patients was, as a rule high, and the fever was often prolonged as long as nine weeks. In only 11 cases was a definitely subnormal stage to be recognized in the convalescence. In 3 cases subnormal temperature was seen only after relapse, but this observation was of no prognostic importance because the subnormal stage was absent in many cases that recovered without relapse, and one case had a relapse although the subnormal stage was definitely marked; 8 typical relapses were seen, a very high percentage. The relapses were usually milder than the original attacks. In one case convalescence was complicated by a pleurisy, and by a course of fever resembling a relapse. It was doubtful in this case whether the condition was really pleurisy alone, or pleurisy and relapse. No definite causes for the relapses could be determined. In one case relapse occurred 18 days after fever had disappeared; the one suspicious sign in this case in the interval was the absence of the usual convalescent rapidity of the pulse. Nervous symptoms were marked, and severe delirium was seen repeatedly. In one case there was severe melancholia at the onset, and for six weeks a peculiar sleepy condition, with scanning speech and mental confusion and with no subsequent memory of this period. An onset with severe delirium indicated a bad prognosis. One striking sign which was repeatedly observed was tonic spasm of the muscles; when this involved the extensors of the arms it was always a sign of a fatal issue. As to the patellar reflexes, it was found that only 3 of 48 cases examined showed increased reflex; in the other cases the reflexes were decidedly decreased, and in 22 absent. The reflex usually became increased in convalescence. Bleeding from the nose was seen in 33% of the cases. Marked stomatitis was seen in the beginning of one case. Herpes was present twice. Albuminuria was seen in 35 cases. In 24 cases there were casts, and in 8 red blood corpuscles. The diazo reaction was negative in 11 cases at the time of admission, though in 11 of these

cases the diagnosis could be made at once from a clinical standpoint. He thinks that the diazo reaction has no definite diagnostic value. As to acetone, he states that while it is often present in the urine it disappears as soon as a proper amount of nourishment is given; **acetonuria is hence the result of inanition.** In 2 afebrile cases the Widal reaction was negative in the beginning. In one of these cases the presence of enlargement of the spleen, initial diarrhea, and the fact that the patient was a permanent guest of the inn where the cases arose led to the diagnosis. In the other case the diagnosis was made from splenic enlargement, bronchitis, typical tongue and typical stools. In both these cases the Widal reaction was ultimately positive. The Widal reaction was used altogether in 24 cases, was positive 20 times, doubtful once, and negative 3 times. In all the latter cases the negative results were obtained before the 11th day. He considers the Widal reaction extremely valuable, though not absolutely reliable. Under treatment, he mentions the regular use of sodium salicylate in the morning when the temperature was high, and likewise quinine was given in the evening. [D. L. E.]

4.—Hellendall has used cerebrospinal fluid from suspicious cases for injection into the spinal canals of guinea pigs, in the hope that by this method it might be possible to cause a rapidly fatal tubercular meningitis in these animals, and in this way to make the diagnosis of tubercular meningitis in human subjects more rapidly than has been possible hitherto. Before carrying out these injections it is well to try the method on the bodies of dead guinea pigs so that one may determine definitely that he is injecting properly and getting the fluid into the spinal canal. The needle needs to be introduced about 1 cm. The result of these injections was very surprising. Microscopic examination as well as gross examination showed that the brain and spinal cord remained entirely free from tuberculosis, but that there was a general tuberculosis of the other organs. In other words, that the injection of fluid containing tubercle bacilli into the spinal canal had produced a miliary tuberculosis, but that the region injected remained entirely free from disease. He believes that there is no doubt that he actually injected into the spinal canal because of the immediate appearance of signs of increased cerebrospinal pressure after the injection, and because in one case there was at the point of injection into the canal a localized area of caseation in which there were large numbers of tubercle bacilli. This method evidently cannot be used in the way in which it was hoped that it might be. He thinks, however, that it may prove of value because the animals died more rapidly than is customary in experimental tuberculosis, and because smaller quantities of fluid can be used; 2 cc. are sufficient when used in this way, while when used intraperitoneally 4 cc. are required. The latter quantity often cannot be obtained during life. [D. L. E.]

5.—Fast refers to the remarkable case reported in the same journal, 1900, No. XXIII (abstracted in *Philadelphia Medical Journal*), and describes a similar case in which there were the usual signs of aneurysm of the aorta just below its passage from the diaphragm, but a loud almost metallic diastolic murmur was heard over the ensiform cartilage, and decreased in intensity as the stethoscope was carried upward. Pressure on the femoral arteries caused the murmur to become louder. There were no arterial signs of aortic insufficiency, and it was decided that the murmur was produced by the aneurysm. The post-mortem examination confirmed this diagnosis. The aortic valves were found to be entirely sufficient to all tests, and an aneurysm was found in the abdominal aorta in the neighborhood of the hiatus. The portion of the aorta just above the aneurysm was decidedly narrow. He believes that the murmur was produced by a backward flow of the blood from the aneurysmal sac through this narrow portion of the aorta. It was not possible for the murmur to have been produced in the sac of the aneurysm itself, because the sac was nearly filled with clot, and the channel through the spindle shaped aneurysm was only about normal size of the aorta. It had been observed in this case that the arteries below the aneurysm showed no abnormal signs. This led to the thought of the possibility of aneurysm of the celiac artery, but the autopsy showed the absence of any such aneurysm. The post mortem showed a large

effusion of blood into the intraperitoneal space which had not been diagnosed during life. It had caused no signs of acute anemia or other severe symptoms. [D. L. E.]

8. Concerning the Demonstration of Minute Amounts of Albumin in the Urine. A. PRAUM.

1.—Binz found a considerable amount of undissolved iron in bottles containing natural iron waters. In investigating the amount actually contained in solution and comparing this with the amount that the waters were supposed to contain, he found that losses of from 1½% up to 98% occurred by precipitation. The iron in the mineral waters is present as a carbonate, in solution in an excess of carbonic acid. If the water loses its carbonic acid and oxygen takes its place, the iron salt is oxidized to the oxydrate, and this salt being insoluble is precipitated out. This is likely to occur when the bottles are filled at the springs, and it would require much care to avoid it. Methods should be introduced to prevent the occurrence of this loss of CO₂. [D. L. E.]

2.—Ostmann recommends cocaineizing the area to be operated upon and searing the vessels with the galvanocautery before undertaking various minor operations on the nasal cavities. It is also a useful method of controlling bleeding from the nasal cavities. [D. L. E.]

3.—Albrand recommends that the patients be taught to use the sound themselves after operations upon the tear duct. The difficulty is, however, that they are likely to grow tired of this, and give it up, and so require renewed dilatation. Valpinus' permanent sound is oftentimes used with much satisfaction, but many patients cannot bear it. It not infrequently causes marked pain in the nose. He considers extirpation of the sac most satisfactory in cases of long duration with more or less profuse muco-purulent secretion, in all cases with fistula, in those with changes in the periosteum and with caries of the bone, and in those resulting from the action of caustics or from trauma, in cases with prolonged conjunctivitis, ulcerations of the lids, and in trachoma. It should also be undertaken in less severe cases in which social reasons indicate its use, i. e., in patients who must work constantly for a livelihood. In such cases it saves the patients much valuable time. He has attempted for prophylactic reasons, as for instance, preceding cataract operations, to close the tear duct by touching the openings with a glowing needle. He never succeeded in this, however. He insists that the nose must always be carefully examined in cases of disease of the tear duct, as not infrequently some nasal condition is the cause of the continuous trouble with the tear duct. [D. L. E.]

4.—The patient was a man of 36 who about three weeks before had had marked emotional excitement, which was followed by jaundice, which had persisted. He had been married one week before he was seen by Albu. He was when seen slightly stupid, had decided fever, was markedly jaundiced, the liver dullness was only about two fingers breadths in width, the splenic dullness was enlarged, and two days later large amounts of leucin and tyrosin were found in the urine. Severe delirium appeared. The spleen became palpable. The fever remained high, with decided irregularities from the 24th of June to the 8th of July; after the latter time it quite rapidly decreased and reached normal on the 13th of July. Leucin and tyrosin persisted in the urine, and were obtained pure by Frerich's method. Apparently these substances were still present when the patient left for his home on July 28. There had been a rapid improvement in the symptoms with the decline in temperature, and by the 14th of July it was noted that the liver dullness was considerably wider than before. Icterus

persisted for a long or two months after the illness, but a month later the patient wrote that he seemed to be in absolutely good health and had no signs of any sort of illness. The supposed relation of the liver to the production of urea led Albu to determine the nitrogen and urea in the urine. The excretion of nitrogen was undoubtedly considerably above the intake, but on one day the urea composed 75% of the total nitrogenous substances, and on another day 85%, not far from the normal amounts. Albu expresses his firm conviction that this was a typical case of yellow atrophy in which regeneration of the liver tissue took place. He refers to Wirsing's report, who in 1882 collected 15 similar cases from the literature, and reported a personal case. Only two other cases besides Albu's seem to have been described. [D. L. E.]

5.—The treatment recommended is the old ipecac treatment. Pléhn has recently recommended the use of calomel in large doses. Ruge has found, however, that this not infrequently causes the symptoms to grow worse. He uses an infusion of four parts ipecac in 160 parts of water, giving about 80 c.c. of this at most, and administering oil of peppermint with it. [D. L. E.]

6.—In investigating the use of Weigert's method, Michéls has looked into the possibility of using other oxidizing agents in place of chloride of iron. He found that it was readily possible to substitute the persulphate of ammonia. The results obtained were quite as satisfactory as those obtained with chloride of iron. He could also substitute other phenols for resorcin, positive results being obtained with orcin, pyrogallol and orthokresol; xanthenes, however, could not be used; fuchsin could be substituted for by a large number of other basic stains, methylene blue alone of those tested apparently having been unsuccessful. Colorless aromatic bases could also be used in the place of dyes; for instance stains were obtained with hydrochloride of anilin, dimethylanilin and paratoluidin. All the eighteen dyes with which he has worked must be used in an HCl-alcohol solution. He gives a list of the different colors obtained with the different stains. In staining sputum he advises smearing the sputum on slides, allowing this to dry in the air, then placing the slide in a cylindrical vessel containing Weigert's solution, the alcohol of the solution producing fixation. Other methods of fixation are unsatisfactory, and formalin in particular can not be used. The slide is removed after a half hour and washed in 3% HCl-alcohol until practically colorless; it is then allowed to dry and the smeared sputum is covered with a large drop of cedar oil, and examined directly without cover-glass. Elastic fibers will appear dark violet, and other substances which before staining are easily confused with elastic fibers will show no stain. He finds that with such staining methods one can often show the presence of elastic fibers when bacilli are absent; hence he considers it a very useful diagnostic procedure. [D. L. E.]

7.—Zuelzer states that previous to the appearance of the recent article by Mertens (Abstracted from Deutsche Medicinische Wochenschrift, 1901 No. XI), he had himself been engaged in similar experiments, and had had the same results. The only difference in his work was that he injected urine subcutaneously while Mertens injected it intravenously. The serum of rabbits treated with albuminous urine gave a specific reaction with human albuminous urine. He, however, modifies Merten's conclusion by stating that this indicates that there is in blood and albuminous urine at least one identical form of albumin. He does not think that the conclusion is justified that the albumin in the urine is derived from the blood. He is making further investigations concerning the chemical nature of the precipitated albumin, and has also carried on investigations concerning the iodine combining power of the albumin with the idea of showing in this way also that the albumin of the urine is identical with that of the blood. [D. L. E.]

8.—The method recommended consists merely in adding to the urine in the test tube a reagent for albumin, the author preferring sulphosalicylic acid and then pouring some of the urine into a filter and allowing the filtered urine to run slowly down the side of the test tube so that it forms a layer above the urine containing the reagent. The latter is heavier because of the presence of a reagent, hence the untested urine floats above that containing the reagent. If a reaction occurs it is readily seen, because

the two layers of urine can be easily compared in this way. [D. L. E.]

1.—Schmidt directs attention to the great tendency to a rapid change in the frequency of the pulse which may be seen in those with neurotic hearts, wave-like changes in the frequency being readily discovered, and being sometimes the only evidence of a cardiac neurosis. The remarkable effect of psychic influences is also notable; many patients indeed by auto-suggestion can cause a marked change in the rapidity of the pulse, the pulse in these persons is readily excited by rapid breathing, by body movements, and by other means. Reflex excitation of the pulse is also frequently noted, as, for instance, pressure on tender points, or slowing when bending far forward. It is also notable that while normal inspiration causes a marked reduction in the force of the pulse, in cardiac neuroses, if the patient inspires slowly and deeply one may often notice an almost complete disappearance of the pulse during inspiration. Sphygmographic curves are given to show this effect. This is apparently largely due to changes in the arterial pressure, but not entirely so. Schmidt believes with Lowit that reflex nervous influences are very important in the production of these changes. Schmidt also directs attention to the frequency with which one may find a crownlike arrangement of enlarged venules about the boundaries of the precordia. These may often be seen along the course of the diaphragm, also in cases of emphysema and similar conditions in which there is a chronic cough, and in persons who have engaged in excessive labor; but he has very frequently noticed the enlargement of the venules about the precordia in persons who have no organic disease, and in such persons it was always learned that their occupation required them to lean many hours a day over a writing table. Schmidt thinks that this position is probably enough to produce an enlargement of the veins, and also to produce the cardiac symptoms. Sahli considers that increase in the pressure of the thoracic contents upon the veins produces the enlargement of the venules, and when a person has an occupation which constantly requires him to bend forward, it may readily be seen that such pressure is much increased. Schmidt also agrees with Hoffmann that the hearts of neurasthenic patients are often extremely movable. He thinks that the position described is probably active in producing an increased movability of the heart as well as in producing symptoms. [D. L. E.]

2.—Mayer notes that glycuronic acid is in chemical composition very similar to glucose, and that it has been strongly suspected by many that it is a product of the oxidation of glucose. It has been said by authorities that glycuronic acid is not found in normal urine. This, he considers, has been shown to be incorrect by the work done by himself and Nenberg, since they were always able to show the presence of considerable amounts of glycuronic acid in normal urine combined with phenol, indol and skatol. He has also investigated the occurrence of larger amounts of glycuronic acid in the urine in certain conditions, and he believes that he has shown that in at least a very large percentage of cases, when the test for sugar is doubtful, or more particularly, when after long heating in the use of the copper test a precipitate occurs, but occurs only after considerable heating, the substance present is really glycuronic acid in excess and not sugar. The most satisfactory method to demonstrate glycuronic acid is to show the bromin-phenylhydrazin compound, but this can be done only when considerable amounts of glycuronic acid are present, that is, when the amounts are pathological. The method which Mayer uses is to heat the urine with acid (as much as 1% of sulphuric acid) in a porcelain dish over a free flame. The boiling should not be continued more than from one to

three infants. The orcin test should then be used, and if the characteristic spectrum is seen one may consider definitely that glycuronic acid is present. Large amounts of glycuronic acid are found after giving glucose for testing the presence of alimentary glycosuria. He mentions 14 cases in which paired glycuronic acid was found with sugar, and 6 in which it was found without sugar, after giving from 100 to 200 gms. of glucose. He has investigated the possibility of discovering glycuronic acid in the blood, and believes that the reducing substances found in the blood are largely of the nature of glycuronic compounds. (To be continued.) [D. L. E.]

3.—Roos presents some studies of metabolism and absorption while plantose was used in connection with a mixed diet, and other periods when plantose was not used. He found that there was a much larger retention of nitrogen when plantose was used than when it was not, and that the substance was well absorbed. He also found that it was well taken by patients, and caused no gastro-intestinal disturbance. [D. L. E.]

4.—The very remarkable case recorded was that of a girl of 23 who had had an injury, but no other apparent cause for the onset of hysteria. She had not chlorosis or other evident serious organic disturbance. The difficulty began with protracted cough followed by marked dyspnea, then by convulsive attacks which became more and more frequent until they occurred almost constantly. They had become somewhat more infrequent, however, a short time before she was seen by Arneith. The most striking fact about the examination of the patient was that she breathed with her mouth open, and purely through the mouth, the breathing being very rapid and being accompanied by a most intense stridor, similar to that seen in marked stenosis of the larynx. There was very striking movement of the alae nasae without the least breathing through the nose. The cause of the dyspnea and stridor was found to be spasm of the aryepiglottic muscles, which drew the epiglottis down against the top of the larynx so firmly that there was only a slight opening through which air could pass. Occasionally she had most terrifying attacks of apnea, each of which was apparently about to lead to death, when after about a minute of the most intense cyanosis and complete apnea breathing began again with the curious stridor, and the previous condition was resumed. During sleep it was noticed that the stridor disappeared completely and air was taken in solely through the nose. An attempt was made to instruct her in breathing through the nose, and after a time was fairly successful, but it had no special influence upon the stridor. The attacks of apnea, became more and more frequent and intubation was adopted, but this did not stop the attacks which were then evidently due to spasm of the respiratory muscles in general. Three days after admission the patient had 38 attacks of apnea within a few hours. The next day the attacks were completely stopped in a most curious manner. v. Leube had ordered inhalations of ammonia in an attempt to increase the respirations during the attack. The result was that the patient sprang out of bed, cried out loudly, and had a most profuse secretion of saliva and mucus from the mouth and nose, as much as a half liter escaping within a short time. It was found that the mucous membranes were of most curiously striking purple red color; evidently the ammonia had had a very intense vaso-motor effect. No attacks occurred that night, but the same stridor recurred, and it was found that it was now due to a bilateral paralysis of the posticus. The swelling of the epiglottis and the intense inflammation evidently made it painful to continue the previous spasm, and a new form of spasm had been adopted for this reason. The old method of production of stridor was, however, adopted once more as soon as the inflammation of the epiglottis had subsided. During the period of inflammation the stomach tube had been used in feeding the patient. It caused her much pain, and she was intensely fearful of it, and threats of the further use of the stomach tube entirely cured her of any tendency to other attacks or to stridor. [D. L. E.]

5.—Leo Schwarz criticizes the recent publication of Blumenthal and Neuberg, (abstracted from *Deutsche Med. Woch.*), who believe that they have demonstrated that acetone may be produced from albumin. The first criticism is that the demonstration of the production of acetone from albumin in the laboratory does not show that such a process does take place in the human organism. Further, the report of the authors mentioned shows that the amounts

of acetone were at best small, and Schwarz believes that the acetone was present in the original gelatin as a contamination, and was probably not produced by the method described. He insists that it is necessary in order to demonstrate their point, that the authors should use a pure crystalline albumin. He has been unable himself with 750 gms. of gelatin to show the presence of any acetone by a similar method, or to produce acetone from egg albumin by oxidation with permanganate of potassium. He has found it impossible to carry out the method described by Blumenthal and Neuberg. [D. L. E.]

6.—Waldvogel, in reply to the criticisms of Rumpel (abstracted from the *Munch. Med. Woch.*, 1901, No. VI), replies that his method was constantly compared with results obtained by the Beckmann apparatus, the latter apparatus being used coincidentally by a colleague. The results were practically exactly the same. Another criticism offered was that there were errors in the dilution. This he believes is not the case, as other dilutions were made coincidentally by colleagues working with him, and their results were compared. He thinks that no error was discoverable. [D. L. E.]

JOURNAL DE CHIRURGIE.

1. The Danger of Morphin Injections After Operation Under Chloroform. LAUWERS.
2. Auto-Intoxication in Intestinal Obstruction. KUKULA.
3. The Pathogeny of Periurethritis. BOISSON.
4. The Treatment of Exstrophy of the Bladder. LORTHOIR.

1.—Lauwers reports the case of a strong man of 18, with a naso-pharyngeal polyp, which obstructed both nares and caused abundant hemorrhage. Operation was performed under chloroform, after an injection of 25 c.c. of antistreptococcic serum the day before. The right external carotid was ligated; the right superior maxilla resected by Kocher's method; the tumor removed; the maxillary bone replaced, with cat-gut sutures; and the wound closed. As the chloroform had been stopped and the patient began to regain consciousness, 1 cg. of morphin was given hypodermatically. Respiration became slower and ceased altogether an hour later. Artificial respiration was at once begun, stimulants and normal salt solution injected, and counterirritation applied to the chest. The patient would not breathe voluntarily, his pupils were contracted, and his pulse 40. After four hours work, without his taking one respiration of his own accord, tracheotomy was performed, and the trachea stimulated, down to its bifurcation, with a gauze tampon, introduced through the tracheotomy opening. This provoked violent expiration, after which breathing began. For an hour this was repeated at intervals; then breathing was re-established. He recovered gradually, the wound healing by first intention. Undoubtedly the morphin, not the chloroform, had produced the symptoms of poisoning. Yet Lauwers believes that the chloroform not only modified the effect of the morphin, but exaggerated it. He reports two more cases, in which death followed the administration of morphin after chloroform anesthesia. From his experience, Lauwers suggests irritating the tracheal mucous membrane as a last resort, when unconsciousness with failure of respiration occurs after chloroform anesthesia. [M. O.]

2.—After a number of unsuccessful experiments, Kukula finally managed to cause intestinal occlusion, by double ligation of the intestine. In seven cases he was able to study the intoxication which followed. Besides, he examined the intestinal contents in a number of human beings who had been operated. In spite of having made over 200 experiments, he does not feel justified in forming any conclusions. It was striking that the intestinal contents, after passing through the Cumberland filter, caused no toxic symptoms in animals. It seems probable, then, that the toxic substances failed to pass through the filter; or they may have been too greatly diluted. Artificial intestinal occlusion showed toxic matter which was not soluble in alcohol. But there is no doubt that unknown toxic substances, injected into the peritoneum of animals, produce intoxication. When any obstacle exists in the intestine, the reaction occurs at once. Yet toxic material exists in the intestines normally. Kukula has found that this material is absorbed in human beings when intestinal oc-

clusion occurs, partly as a gas, and partly as a watery solution. [M. O.]

3.—By *perilurethritis* Holston means any infection which starts from the urethra, and affects the surrounding tissues. In all cases, anaerobic bacteria have been found with or without aerobic microorganisms. The mildest form is follicular *perilurethritis* or folliculitis, small cysts forming along the urethra, with urethritis, easily cured by incision; or acute or subacute circumscribed *perilurethritis* may occur, called formerly *perilurethral abscess*. Prostatitis or *cowperitis* may accompany it. Incision with drainage will be necessary. Chronic or sclerosing circumscribed *perilurethritis* is rare. These forms may become diffuse phlegmonous *perilurethritis* which was formerly called pseudo-urinary infiltration. And this may later become diffuse gangrenous *perilurethritis*, when urinary infiltration occurs. This is always dangerous and needs immediate operation. Most rare of all is chronic or sclerosing diffuse *perilurethritis*, following long standing *bleenorhagia*, etc. All grades of *perilurethritis* are due to microbes traveling from the urethra and setting up infectious inflammation as they go. *Perilurethritis* seems to have a tendency to destroy the aponeuroses and muscles of the perineum on its way to the ischio-rectal fossa. A full review of the literature is given, and the histories of 16 reported cases follow. [M. O.]

4.—Lortholoz, who has seen four cases of *exstrophy of the bladder*, has operated upon three of them. The first case was three months old, a girl who recovered from the operation, with incontinence of urine. At 13 months she died with pneumonia. The second case, a girl of two months, was operated, by a method nearly that of Wood and Segond, successfully, but died with marasmus several months later. In the third case, a boy of two years, the operation was palliative only. He is still alive and well, and wears a urinal constantly. After a full description of the technique of both Segond's and Nota's methods of operating, Lortholoz describes two of Nota's successful cases. Photographs and diagrams accompany the article to explain the technique of the operation. [M. O.]

1.—A historical review of the operative treatment employed in carcinoma of the stomach.

3.—E. Friedländer reports a case of *stramonium poisoning* occurring in a coachman 44 years of age, who was suffering from asthma. Someone had recommended that the patient should employ dry leaves of *stramonium* to relieve his suffering, but the patient took the remedy internally by mistake. A few minutes later there was a marked burning in the throat and a feeling resembling asphyxiation, followed by unconsciousness. On admission to the hospital one hour later, the face of the patient was cyanotic, respiration 50 per minute, pulse 96, and some mucous rales were heard in the chest. There was some flow of saliva, the pupils were dilated ad maximum, but consciousness was fully restored. Under the administration of coffee and mild alcoholic stimulants he recovered about the fourth day, although the pain in the throat persisted for some time thereafter.

4.—The author believes that diphtheria organisms can be positively demonstrated by methods of staining. He describes the following method: From a culture of bacilli from fifteen to twenty-four hours old, grown, at a temperature of 37.7° C. on either glycerin-sugar or Loeffler's blood serum, dry cover glass preparations are made and stained with methyl-blue for twenty to thirty seconds. Decolorization is effected by holding for five seconds in a three per cent solution of hydrochloric acid alcohol, and the counter stain is produced by dipping for five seconds in a one per cent aqueous solution of eosin. The polar nuclei are

by this method sharply stained, while the central portion takes a red color, which is more marked, than with the vesuvin stain generally used. [M. R. D.]

11. Dr. August Brauser. MAYER.

1.—In case of *congenital narrow pelvis* it is important to maintain the integrity of the membranes as long as possible, and to secure, if possible, complete dilatation of the os uteri. For this purpose the *colpeurynter* should be employed without hesitation. The statistics for the Dresden clinic show that in 1187 births in 4 years version was employed 105 times, that is, little less than once in 11 births, and that in 60 of these cases the pelvis was narrow. In the normal cases the results were one death in 45; 2 cases of slight infection, and three of moderate injury to the genitalia. Of the children, 16 were dead at birth, and 2 died in the first 10 days. Twenty-nine were discharged alive. Of these 16, 9 were extracted dead on account of *placenta praevia*. In the cases of narrow pelvis one woman died in 60 cases, and 4 had a moderate infection. Of the children, 9 were born dead, and 3 died a few days after birth. Forty-eight of 60 were discharged alive. Albert calls attention to the fact that in narrow pelvises version is rarely done upon primipara on account of the greater capacity of the head for moulding. [J. S.]

2.—Dieudonne has injected rabbits with human blood serum, albuminous urine and pleural exudate. About 10 ccm. were injected every 2 or 3 days. It was found that when the blood solutions of Uhlenhuth were employed, consisting of one part blood to 100 parts water, the mixture being filtered, and 2 ccm. of this mixed with 4 ccm. of physiological salt solution, and then 6 drops of serum was added, that curious reactions occurred. If the serum of a rabbit treated with human blood was used a precipitate occurred in a few minutes. Normal rabbit serum failed to give this, and the reaction was entirely negative with the serum of guinea-pigs, pigeons and geese. The serum of a rabbit treated with albuminous urine gave a precipitate upon the addition of albuminous human urine, but not with human blood serum. The serum of a rabbit treated with a pleural exudate, showed a precipitate with the fluid of this pleural exudate, but not with the serum of normal rabbit blood. It was also found that the serum of a rabbit injected with human blood serum gave a precipitate with the albuminous urine and the pleural exudate, but this precipitate was not as distinct as with the blood. The same was true of the sera obtained with the urine and exudate. In no case did the sera obtained from the lower animals react with the rabbit sera produced by the injection of human products. For medico-legal use of dieudonne specially recommends the employment of rabbits immunized with human blood serum. [J. S.]

3.—Rosenbach calls attention to the fact that *unilateral pleural transudations* may occur as a result of weakness of the heart, or even isolated congestion of the liver followed by ascites, and an acute congestion of the liver may result from weakness of the heart after such infectious diseases as diphtheria. He has endeavored to find some method of distinguishing between transudates and exudates, and has

discovered that salicylic acid or iodine passed rapidly and in a considerable quantity into transudate and only in small quantities into exudate. He believes, however, that there are transitory stages between hydrothorax and pleurisy. [J. S.]

4. Hermann has studied the disease to which laborers working in chemical factories in which bichromate of potassium is prepared, are exposed. These affect generally the gastro-intestinal tract, the kidneys, and the respiratory apparatus. The most important are those involving the nose. These lead first to irritation of the nasal mucous membranes, then to ulceration, and finally to perforation of the cartilage. Statistics show that after 6 months very few of the workmen have healthy noses, and that perforation occurs in the majority at this time, and in those men who have worked more than a year, perforation is the rule. The cause of the situation of the ulcer is probably the continual application of the dust of the chromium salts to this portion of the nose with the finger. Injuries to the larynx and lungs are exceedingly rare, the commonest other disease being persistent eczema of the hands and feet. In 12 cases in the course of 2½ years slight disturbances of digestion usually associated with diarrhea were observed, and these possibly were not ascribable to the bichromate. In his experience albuminuria did not occur. He suggests as a prophylactic first, that the workmen be instructed in personal cleanliness, and second, that they use some form of respiratory filter, recommending one constructed of albuminum, in which the filter consists of cotton wool. [J. S.]

5.—Ghillini discusses the advantages of operation for the relief of congenital luxation of the hip, and calls attention to a girl of 18 that he presented to the Surgical Society in Rome in October, 1897, who had suffered from bilateral dislocation of the hip, and had been operated upon according to Ghillini's own method 3 years previously. The results were quite satisfactory; the patient was able to walk well, and only limped slightly on the left side. [J. S.]

6.—The patient, a woman of 69, without previous history, had been emaciating for three months. Suddenly, while sleeping, she was attacked with severe pain in the epigastrium with distension of the upper portion of the abdomen, followed by vomiting of liquid masses that had a fecal odor. She refused operation and died in 36 hours of collapse. At the autopsy there was found a purulent peritonitis, and multiple fat necrosis in the serous membranes of the intestines. The pancreas was normal. The interesting features of the case were the typical symptoms of occlusion of the intestine and the existence of peritonitis without assignable cause excepting the fat necrosis. It is probable that some septic complication also existed.

7.—Barth reports the case of a man 55 years of age, who subsequent to an attack of whooping-cough had continual coughing and oppression in the chest. He received at the age of 48 a severe injury to the chest by being trodden upon by a horse, and from this time the oppression in the chest became very severe. Finally the typical symptoms of aneurysm of the ascending portion of the aorta developed. It was decided, therefore, to treat him with injections of gelatine. A one per cent. solution was employed, 100 grms. being injected on alternate days until 12 injections had been made. At the same time the patient was kept in bed and potassium iodide was administered, cold was applied to the chest, and a moderate diet given. The tumor rapidly diminished in size, ceased pulsating, and the rough aneurysmal bruit became very much less. Later he was given a second gelatine cure, using this time a solution increasing in strength from 2 to 5%. The subjective symptoms, with the exception of slight dyspnoea, disappeared completely. [J. S.]

8.—Lacher reports the case of a man who as a result of chronic empyema developed marked swelling of the end phalanges of the fingers and toes, involving exclusively the soft parts. An operation was performed that reduced considerably the size of the abscess cavity, and as a result, the breadth of one thumb diminished from 3.2 cm. to 2.7 cm. and the other fingers in proportion. [J. S.]

9.—Gunzberger reports the case of a boy 13 years of age who had a severe attack of urticaria, which in the course of a few days was followed by edema of the face. An examination of the urine showed a moderate amount of albuminuria. Casts were not found. The patient rapidly recovered. [J. S.]

1.—The following 2 cases of acute serous meningitis complicating disease of the middle ear, are of exceptional interest. The first, a man of 32, had chronic otitis media with perforation of the membrane. He was suddenly attacked with severe headache, which at first was intermittent, but after 10 days became constant. He had vertigo and severe pain in the left ear. An examination of the eyes revealed neuritis of the optic nerve on the right side, with beginning changes of the left side. The ears showed the characteristic changes. There was some vomiting, subnormal temperature, and bradycardia. As operation was indicated both mastoid processes were opened, the brain was exposed, the dura incised and 5 ccm. of clear serous fluid was immediately evacuated. There was instant relief; the pulse increased from 44 to 58 and the temperature rose slightly. An enormous amount of serous fluid was persistently discharged from the wound, probably in excess of 0.5 litre daily. The patient gradually improved and was discharged completely recovered. The 2nd case, a man of 24, had had a discharge from the right ear from childhood. When admitted the temperature was slightly subnormal, and the pulse was 88. A similar operation was performed. The brain appeared to be normal and the dura was not incised. Subsequently the patient's condition grew worse; there were symptoms of pressure and therefore a second operation was performed. The brain was freely exposed, and the tense dura incised. A considerable quantity of cerebro-spinal fluid was immediately discharged, the patient in a short time recovered consciousness, and seemed very much better. An enormous quantity of cerebro-spinal fluid was discharged but the subsequent course of the case was favorable and the patient recovered. The interesting point is the brilliant results of operative interference. [J. S.]

2.—Klebs in discussing infection of the intestinal tract, mentions the frequency with which scrofulous affections of this system precede the actual outbreak of tuberculosis. As the tubercle bacilli are usually introduced in some vehicle, it is not impossible, provided they multiply in this, that a certain amount of toxin has been formed so that an intoxication accompanies the infection. One of the most suspicious of all foods is butter. His experience has been that children habituated to an excessive consumption of butter are either slender or else fat but anemic. Butter also tends to cause furunculosis. He mentions 2 cases of eczema that he observed, produced by a very small diplococcus. Ten years later Klebs, who had been one of the cases of eczema, developed multiple lesions, eczema of the hands and ulcers on the legs, etc., which he ascribed to excessive indulgence in butter. He believes that his system was weakened by the toxins present in that substance. He therefore injected guinea-pigs with liquid butter, and the animals died the same night, without presenting any symptoms at the autopsy. Another pig lived 3 days, the autopsy showing only congestion of the organs. He regards these results as similar to those obtained by the injection of tuberculosis toxins. In both cases there was marked reduction in the body temperature. In the 3rd case the temperature dropped from 38° to 30°. The animal lived 2 days. The paper is still unfinished. [J. S.]

3.—Oppenheimer, after a careful review of the various experiments of Ostwald, Bradig, Fischer, Ehrlich, and others, concludes as follows. If the catalytic action of the organic sub-stratum can be separated from the proper ferment action, and if the ferment processes do not exactly follow the laws of catalysis, then a very essential thing in favor of the specificity of these processes is neglected, that is, the preliminary steric combination of a ferment on the substance. Moreover, the recognition of the ferment as a secretion is entirely overlooked. Ferments have a pecu-

ilar character that belongs exclusively to themselves. It depends upon the preliminary sterile combination of the ferment with the substance, and a subsequent separation for which the selenketon theory gives an adequate hypothetical explanation. [J. S.]

4.—Hollisberger has employed adrenal extract in 20 cases of rickets. He employed the tablets of Burroughs, Wellcome & Co., and administered daily as many centigrams as the child weighed in kilograms. The results were disappointing. A progressive improvement in the symptoms occurred in only one case and in 2 cases the patients grew worse. A temporary improvement occurred in the majority of cases. However, the disagreeable odor of the urine was not improved. In only 3 cases was the cutting of the teeth promoted, but in 10 cases there was a moderate improvement in the shape of the head, and in 3 cases the anterior fontanelles grew smaller. The history of 9 cases follows. [J. S.]

5.—Hulsmans reports a case of Addison's disease occurring in a girl of 20 years of age, who had had tuberculosis of the cervical glands and at the time of death had distinct evidence of tuberculosis of the lungs. There was a brownish discoloration of the skin and extreme anemia. At the autopsy both adrenal bodies were found infected with tuberculosis. The author believes that the object of the adrenal bodies is to absorb certain toxic substances manufactured in the intestines. [J. S.]

6.—Steinhardt believes that gastric lavage is of great value in young children, to control vomiting and diarrhea, particularly when these are the result of acute gastroenteritis. He has employed it altogether in 46 cases ranging from 5 weeks to 2 years of age. Children are usually much less affected by this procedure than are adults. Occasionally they struggle and retch but not often. The tube may be introduced through the mouth when it is rather likely to produce nausea, or through the nose, when it rarely produces any disturbance. An ordinary catheter, either No. 6, 8 or 10, may be employed. He reports 2 cases in which vomiting occurred only once as a result of the prompt employment of the lavage, and others in which the lavage stopped vomiting which had persisted for some time. [J. S.]

7.—Sallid calls attention to *sidenol*, a combination of china oil and piperazin, which, he believes, is very effective in dissolving and rendering innocuous an excess of uric acid. Having first tried it upon himself, and found that in doses of 1 gm. 7 times a day, no unpleasant results were experienced he tried it in 4 cases of gout with excellent results, and in 1 case of acute articular rheumatism without any benefit at all. [J. S.]

8.—In the course of the year 12,700 children visited the Dispensary for Children's Diseases, at Reisingerlanum. The commonest diseases were those involving the organs of respiration and digestion. [J. S.]

9.—Hörning criticizes Passler's article upon the treatment of croupous pneumonia. He believes that the most serious feature of this disease is the intoxication which appears to work directly upon the vasomotors. For this reason alcohol is contra-indicated. He strongly recommends faradism, placing the large electrode over the heart and using a rolling electrode for the rest of the body. This stimulates the vasomotor centres, causing contractions in the small muscles and acts as a sort of massage and is agreeable to the patients. [J. S.]

1.—Baumler reports a very interesting case of compression of the intestine against the spinal column with the causation of acute obstruction. A woman 25 years of age was suffering from typhoid fever complicated by hemorrhagic nephritis. She gradually improved but during the 7th week of the disease suddenly developed pain in the abdomen and vomiting. The vomitus contained a considerable quantity of bile. There were no localizing symptoms. On the same day the patient had had two liquid movements. There was visible peristalsis in the region of the stomach, but, on account of the weak condition of the patient, an operation was not attempted. The urine contained an excessive quantity of indican. Life was maintained for 12 days by nutritive enematas and hypodermic injections. At the autopsy the stomach was found greatly dilated, the intestines were collapsed, the transverse colon descended to the upper border of the pelvis. At the junction of the duodenum and jejunum there was an area of necrosis and obstruction. Baumler believes that it is very likely that the dilated and possibly somewhat depressed stomach had compressed this portion of the intestine against the spinal column and that the further dilatation of the stomach and the descent of the intestine into the pelvic cavity had accentuated the obstruction. In such cases it is therefore desirable to adopt the treatment of Schnitz and Müller, which consists of lavage of the stomach and elevation of the pelvis. A second case that was admitted, a man of 36, suffering from severe sciatica, suddenly developed vomiting of masses deeply stained with bile. The examination disclosed a greatly dilated stomach, and as uremia and locomotor-ataxia were excluded, there was reason to suspect occlusion of the intestine. Gastric lavage was therefore practiced for 15 minutes at intervals of 2 hours each, the patient being in a knee-chest position. The stomach readily became reduced in size, the symptoms of stenosis disappeared and the patient recovered. In conclusion the author tabulated the various malformations of the abdominal contents that predispose to this lesion. They are: abnormal lesion of the mesentery of the small intestine; (2) gastropnoia; (3) enteropnoia; (4) the position of the duodeno-jejuno boundary in relation to the spinal column; (5) pronounced lordosis of the lumbar vertebrae; (6) gastric emaculation and weakness from persistent infectious diseases; (7) chronic dilatation of the stomach as a result of congenital necrosis of the pylorus; (8) prolonged lying on the back after operations; (9) extreme evacuation of the intestines before an operation. The exciting causes are: overfilling of the stomach; (2) chloroform narcosis; (3) compression of the biliary ducts; (4) various gynecological laparotomies; (5) compression of the thorax by a plaster corset. The treatment is that already described. First empty the stomach. 2nd, elevation of the pelvis, particularly while lavage is being practiced, so that the intestines can rise to the upper portion of the abdominal cavity. 3rd, possibly the administration of olive oil through the stomach tube after lavage. 4th, very cautious distension of the stomach with air. If all these fail gastric enterostomy should be performed. After recovery the patient should be for a long time careful of the diet—should take small quantities of soft food, and occasionally submit to lavage. As prophylaxis patients who have any predisposing conditions should be careful not to overfill the stomach, and those who have been chloroformed should be watched carefully for some time. [J. S.]

2.—For a year the patient had been losing appetite, had occasional vomiting and irregular bowel movements, was slender and emaciated, with moderate distension of the abdomen. Two days before admission he had had severe pains in the abdomen, and vomiting after every attempt to take nourishment, with complete cessation of bowel movements. On the 5th day of this condition he was given 1-6 gr. of atropine hypodermatically in 3 doses. The patient died the same day. A diagnosis had been made of carcinoma of the intestine, but at the autopsy it was found that there was a carcinoma at the pylorus. Another case, a woman 56 years of age, had had chronic constipation and attacks of colic. When first seen she had had no movement for 3 days and had vomited twice. There was a

large tumor in the inguinal region, tender upon pressure, which could not be pressed back into the abdominal cavity. The patient was given calomel and an enema. The latter produced a large movement. She was therefore given 24 gr. of atropine in two doses on the 5th day, and on the 6th day a third dose of 1-10 gr. On the same day an operation was performed and the tumor found to be an incarcerated gangrenous hernia. The patient was very restless the following night, and succeeded in dislodging the bandage which had been placed over the coil of the intestines, and she died the same evening. Boffinger believes that the atropine exerted a distinctly unfavorable effect upon this patient. [J. S.]

3.—Adam reports the case of a man 67 years of age, who had been attacked with pain in the abdomen, loss of appetite, constipation and vomiting. The ordinary laxatives had had no effect. The patient had a scrotal hernia of the right side. Opium and ice having produced no benefit, the patient was given on the 6th day, olive oil and 1-20 of a gr. of atropine hypodermatically. The following 2 days the olive oil was continued in considerable quantities and well retained, and on the evening of the second the patient had a profuse evacuation of the bowels with subsequent complete convalescence. [J. S.]

4.—Gäntgens reports the case of a woman 64 years of age who had pains in the abdomen and constipation. As there were signs of collapse the patient was given 1-20 gr. of atropine subcutaneously. This relieved the pains, but caused the characteristic symptoms of atropine poisoning. As, however, there was no movement of the bowels, she received a second injection of 1-21 gr. The symptoms of poisoning were still more severe, but in a few hours she had a very fetid evacuation of the bowels. Extract of belladonna was given in doses of $\frac{1}{4}$ gr. every 4 hours by the mouth. The patient recovered completely. [J. S.]

5.—Middeldorpf reports the case of a man 58 years of age who had indican, albumen and bile in the urine, and the characteristic symptoms of intestinal obstruction with fecal vomiting. As lavage of the stomach and colon was without effect the patient was given 1-6 gr. of atropine in three doses. There were characteristic symptoms of poisoning, and a large evacuation of the bowels. The patient recovered. [J. S.]

6.—Beck reports a series of 7 cases in which as a result of neglect fractures had healed in a vicious position. In all of these cases the Röntgen rays were used to make the diagnosis, and to control the treatment. In the first case there was fracture of the neck of the humerus; in the second, of the femur; the third, of the lower end of the humerus; in the fourth, of the elbow-joint; the fifth, of the shoulder, the 3rd and 4th ribs, and the right radius; in the sixth, the right calcaneus; in the seventh, of the lower end of the radius. A series of excellent illustrations accompany the article. [J. S.]

7.—Knapp reports 16 cases of childbirth in which for various reasons it was necessary to amputate the body of the child and then extract the head. This was usually accomplished very readily, either by hooking the finger in the mouth, or by the use of the cranioclast. In the 16th case continued spasms of the cervix rendered the extraction of the child very difficult. Evisceration was finally accomplished by amputation of the body, and finally after prolonged effort, the removal of the head and placenta. The operation lasted 3 hours. The woman died one hour later. [J. S.]

8.—Cramer reports 2 cases. A woman 42 years of age in whom a spasm of the cervix prevented the extraction of the head, perforation of the infantile cranium was therefore made with the fingers through the eyes, and the head extracted. The patient recovered. In the 2nd case, the patient was brought after one and a half hours journey on the railroad to his office, with the history that the body had been amputated at the neck, and the head left in the uterine cavity. This was readily confirmed. The head was extracted by the same method as was the other, that is, insertion of the index finger through one orbital cavity into the brain, and then the middle finger of the same hand through the other orbit. He finally gives a brief report of a 3rd case in which after version spasm of the cervix prevented the extraction of the head beyond the orbits. The child respired and cried, and therefore all efforts at forcible ex-

traction were abandoned for 5 minutes, when the spasm relaxed and the child was born. [J. S.]

9.—Doerfler believes that amputation for infected wounds when there are symptoms of septicemia, is useless. He believes that all punctured or lacerated wounds should be treated with moist aseptic or antiseptic bandages in order to allow free egress to any germs that may have entered. In cases of actually developed phlegmonous infection deep broad incisions are required. He reports the case of a physician who infected himself in making an autopsy, and upon whom incisions were made from the shoulder to the tip of the finger. As the inflammation spread to the breast and back, incisions were also made to the spinal column and to the sternum. The patient ultimately recovered. The paper is still unfinished. [J. S.]

10.—Neuberger calls attention to the fact that under certain circumstances skin diseases may render their possessors incapable of work. This is particularly true of lichen rubar during the paroxysms of pruritus, (Certain forms of treatment, as for example, antiseptic pastes, acetic acid clay) in various parasitic sychoses may prevent the patient from attending properly to his work. In other cases, as in impetigo contagiosa energetic treatment requires the presence of the patient in the hospital. [J. S.]

11.—Landau discusses the various conditions that affect the period of inability to work after severe sickness. All these cases should be carefully examined in order to determine if possible, the amount of depression of the vital forces. Laborers doing their work at home ordinarily can commence sooner than others, because they have a greater control of their time, and can spend a certain portion of the day in rest. [J. S.]

12.—Kiefer discusses a variety of accidents in which it was questionable whether or not the injury could be ascribed to the nature of the work. He believes that cases of septic infection resulting from injuries more or less inevitable in the calling, should be regarded as accidents worthy of damage. It is more doubtful when the patient is predisposed to certain forms of infection such as tuberculosis. Hernias come under this class to a certain extent, that is, the traumatic forms. [J. S.]

13.—Klebs discusses the tuberculides that he believes are associated with tuberculosis. He recognizes 3 types: first the miliary form of lichen; second, a form which occurs as symmetrical red spots, or appears either as erythema, urticaria, or erythema nodosum, and sometimes leads to the formation of blisters, but soon disappears, and finally, third, furunculosis of patients suffering with tuberculosis. Pityriasis seems to precede tuberculosis in many cases. Finally Klebs speaks of a disease form which may vary from an erythema induratum to a condition resembling moist eczema. He reports the case of a boy who had a tuberculide of the eye and face, which was cured by treatment with TC, commencing with the administration of 2 drops of a 1% solution, increasing slowly to 10 drops. He believes that these tuberculides are really the results of toxic infection. [J. S.]

April 30, 1901.

1. The Action of Bactericidal Sera. M. NEISSER and F. WECHSERG.
2. Blood, Body Cells and Bacteria. L. HEIM.
3. Extra-Cranial Disturbance of the Eyes in Syphilis. O. SCHWARTZ.
4. Lobster Poisoning. GEORGH.
5. Suggestion for the Prevention of Spontaneous Extubation. E. SCHLECHTENDAHN.
6. Septicemia and Amputation. H. DOERFLER.
7. The Relation of Accident to Occupation. E. KIEFER.

1.—Neisser and Wechsberg have performed a series of investigations upon the effect of the mixture of various kinds of active and inactive bactericidal sera. Starting with the fact that appears to have been sufficiently established, that in certain cases excessive doses of immunizing serum may have an injurious effect, they commenced a series of investigations using their bioscopic method, and counting the number of colonies on plates. About .0002 ccm. of a one day bouillon culture of the organism in question, was placed in each of a row of sterile tubes. To this were added various amounts of an immune serum that had been rendered inactive by exposure to 56° and then the re-

quired quantity of the completing active serum. Normal salt solution and 3 drops of bouillon were added to each tube. The first organism was the vibrio of Metschnikoff. Immune serum had no effect when added 0.3 of a ccm. of active rabbit serum, but if the immune and the active rabbit serum were both added the germs died. If, however, too much immune serum was employed the bactericidal effect of the rabbit serum was diminished, and in time disappeared completely. If, to active goat serum, inactive immune serum was added in sufficient quantity its bactericidal effect was destroyed. The authors attempt to explain this by a theory which they illustrate with very ingenious diagrams, basing their explanation upon the Ehrlich-Morgenroth hypothesis. If we suppose each bacterium to have a certain number of equivalents, it will, when injected into the body of an animal, cause to be produced in the serum of that animal a certain number of other bodies which are capable of saturating these equivalents. These other bodies have a function of acting as links in the fusion of different things, and therefore may be regarded as having 2 equivalents, one for the bacteria and one for certain other bodies that also develop in the serum, and resembles ferments, and are capable of absorbing the bodies of the bacteria when both valences of the linking bodies are saturated. If now, by the addition of various substances, we increase the number of combined bodies, then it will either increase, decrease, or fail to effect the bactericidal qualities of the blood. The latter will be the case if the excess of combined bodies remain unsaturated; decrease occurs if some of the bodies are combined with the ferments, and others with the bacteria. It may be that in animals that have been rendered excessively immune, this superfluity of combined bodies may sometimes exist, and the manifestations of immunity are therefore prevented. They believe that their experiments destroy the theory of Bordet. [J. S.]

2.—Helm has made various experiments in order to determine the bactericidal action of normal blood, and to what it is due. By a careful study for a series of days, of hanging drops that had been injected with typhoid bacilli, he observed that in some cases in which the blood had been heated to 60°, or in which small fragments of tissue had been placed, that the bacteria became dissolved after a certain period. He ascribes this to the formation in the hanging drops of some substance produced by the bacteria itself, that is, a bactericidal action that is not due to an alexin, and which is not formed until the alexins have been conquered by the growth of the bacteria. [J. S.]

3.—Schwartz discusses briefly the important syphilitic diseases of the eye-lids. Among them are chancre, which is quite frequent; gummas, tertiary papulas, and occasionally acute syphilitic tarsitis which may develop before the outbreak of the general manifestation of the disease, and chronic syphilitic tarsitis which belongs to the gummatous stage. Tarsitis occasionally occurs in hereditary syphilis. The conjunctiva may exhibit papules or follicles, a condition that resembles trachoma and gummas. In the orbit there may be syphilitic periostitis which may cause exophthalmus or paralysis of the muscles of the eye if it involves the orbital fissure, and give rise to ptosis, diplopia, etc. If the optic nerve is involved there may be optic neuritis. If the muscles are paralyzed before the periostitis occurs it is an indication of a basillary meningitis. The tear-glands are sometimes affected by gummatous infiltration. The cornea may show interstitial keratitis either at the border or in the centre, and with or without development of blood vessels. The central type is more common in the acquired syphilis of adults. It is particularly in this disease that the energetic administration of quicksilver is of use. Occasionally punctate keratitis may occur and even kerato-malacia. The latter especially in hereditary cases. Scleritis and gummatous tumors may occur in the sclera. The most common form of syphilitic disease of the eyes is iritis. This occurs in various forms. Irido-cyclitis, gummatous cyclitis and serous iritis and chronic irido-choroiditis. A case of the latter condition is reported. Gummas sometimes appear in the ciliary body. [J. S.]

4.—Georgi reports a case of lobster poisoning that occurred in a group of men varying from 18 to 22 years of age. All recovered. Those who vomited earliest had the less severe attacks. In the absence of a stomach tube, he made them drink large quantities of milk and carbonated water; this produced prompt emesis and the evacuation of the stomach contents. There is much reason to believe that the lobster was spoiled before being served. [J. S.]

5.—In order to avoid extubation Schlechtendahl carries the thread attached to the tube through the nose. The ends are then fastened to the alve with plaster. The manoeuvre is very readily accomplished by means of Beloeq's cannula, after the tube has been put in place, and the thread brought out between the teeth. The advantages are that the child is unable to bite the thread, or dislocate the tube by movements with the tongue. [J. S.]

6.—Doerfler continues his article upon the dangers of septic infection and the relief to be expected from amputation. He believes that the latter operation only contributes to the exhaustion of the patient and therefore to the fatal result. He mentions a case of a man who was injured by a gun shot, a considerable number of foreign bodies entering the wound, who was treated 8 hours later by a physician, who cleaned the wound as thoroughly as possible, and when all appeared to be going well the man developed tetanus and died. The physician was prosecuted for insufficient cleansing of the wound. It is possible that in this case immediate amputation might not have hindered the fatal result, and on the other hand it is possible that the patient might have had a very severe infection with recovery. The author has studied septic infection upon himself, and describes the symptoms as follows. At first a feeling of lassitude, then the following day sometimes no fever, sometimes slight fever with chilliness. On the 3rd day, pain at the point of infection, and usually some swelling of the neighboring glands. On the 4th day either the symptoms are decreasing, or furuncles begin to appear upon the arm. In practically all his attacks the wound was thoroughly cleansed from $\frac{1}{2}$ to $1\frac{1}{2}$ hours after its reception. When these injuries are not treated antiseptically the symptoms rapidly grow worse. In conclusion he states that there is no such thing as local sepsis without immediate participation of the whole organism. Amputation in these cases is not to be considered excepting those parts that have become gangrenous. Therefore the general teaching that it is desirable to amputate in progressive phlegmonous inflammation should be altered. [J. S.]

7.—Kiefer discusses the great difficulty experienced in those cases in which apoplexy or sudden failure of the heart occurs as a result of over-exercise during work. The responsibility of work for the development of aneurysms is also very difficult to determine, because the symptoms usually develop only after the aneurysm has reached a definite size. Among the other conditions that give rise to difficulty are frost bite, various poisonings, and epilepsy. The latter can only be produced by work as a result of some reflex irritation, as injury to the brain or skull; or as a result of some nervous influence upon a person predisposed. Another nervous condition is traumatic neurosis, and in some cases it may be possible that suicide results from accident. The amount of indemnity that a workman should receive depends a good deal upon the nature of his work. Thus, a man engaged in some delicate manual occupation should receive more for a serious injury to the finger than an ordinary day laborer. Moreover, the ability of a patient to work depending upon his age, skill, intelligence, etc., should be taken into consideration. The author calls attention to the extraordinary statements made by some physicians in their certificates, and in conclusion he urges the great importance of more care in this respect and in particular, of a more thorough study of the nature of injuries and their ultimate results, from the fact that more than 400,000 requests for indemnity were received in the year 1899, and over 100,000 indemnities were paid. [J. S.]

WIENER KLINISCHE WOCHENSCHRIFT.

April 25, 1901. (XIV Jahrgang, No. 17).

1. Senile Atrophy of the Brain a Cause of Tumor Symptoms. A. PICK.
2. The Roentgen Apparatus in the Examination of Healthy and Diseased Vertebrae. ROBERT KIENBOECK.
3. The Atropin Treatment of Ileus. F. POLACK.

1.—Pick reports another case of brain atrophy, in which the symptoms closely resembled brain tumor. A woman aged 59 had grown gradually stupid for six years. Her memory failed and aphasia developed. She could no longer talk or read sensibly. There was no paralysis, the pupils reacted normally, the eye grounds, sensibility, knee jerks, etc., were all normal. Pneumonia occurred with death. The autopsy showed general brain atrophy, most marked in the

left hemisphere. Pick believes that brain atrophy, occurring near a hemorrhage, will explain the mixed symptoms often found. [M. O.]

2.—By using the improved Roentgen apparatus, Klenboeck has photographed normal and abnormal vertebrae. The cervical vertebrae may be taken anteriorly, or from either side; the dorsal vertebrae anteriorly or obliquely sidewise; the lumbar vertebrae from in front or from behind. Luxations and fractures, scoliosis, congenital anomalies, ankylosis, tumors, especially gummata, tuberculous spondylitis, etc., are all well understood from the Roentgen photographs. Among the photographs illustrating Klenboeck's article are scoliosis in a child of 8, kyphosis in one of 2, and dorsal and lumbar Pott's disease in other children. The technique of the Roentgen photography is given. [M. O.]

3.—Polack reports a case of ileus in a woman of 68 years, with great weakness, emaciation, and Trousseau's spots. She vomited everything. As she was too ill for operation, Ortner advised giving atropin injections. The bowels were moved soon after the first injection, and she recovered in the next three weeks. [M. O.]

CENTRALBLATT FUER CHIRURGIE.

April 6, 1901. (28 Jahrgang, No. 14).

1. The Treatment of Luxations of the Lower Jaw which Cannot be Replaced. KRAMER.

1.—As treatment for those rare dislocations of the lower jaw which cannot be replaced, modern surgery, in the text-books and periodicals, recommends only the removal of the condyloid process of the inferior maxilla. But Kramer says that this should only be done as the last resort. He reports a case treated two years ago, in a girl of 20, in whom he simply divided the masseter and pterygoid muscles, not opening the joint at all. This dislocation had existed for five weeks. After the skin had been incised, and the muscles divided, the lower jaw was easily replaced, the muscles sutured, and the wound closed. In two weeks she could open her mouth 2 cm., and since then she has wholly recovered. If this should not be successful, then the condyloid process of the inferior maxillary bone should be removed. [M. O.]

April 13, 1901. (28 Jahrgang, No. 15).

1. An Absorbable Anastomosis Button of Magnesium V. CHLUMSKY.

1.—The great failure of the Murphy button in intestinal anastomosis is due to the button not being absorbed. Chlumsky has manufactured such a button of magnesium, which is gradually absorbed, on all sides regularly, very small fragments only being left. This button decreases in the six days following operation to half its size, and disappears entirely from 10 to 16 days. To hasten its absorption Chlumsky advises giving the patient dilute hydrochloric acid. That it works well has been noted in a patient who died with double pneumonia, four days after operation in which the new magnesium button had been used in a gastro-enterostomy. [M. O.]

April 20, 1901. (28 Jahrgang, No. 16).

1. The Surgical Value of the Aluminum-bronze Wire Suture. RUDOLF PICHLER.

1.—Aluminum-bronze wire is composed of about 85% copper, and 5% aluminum. From culture experiments upon Pétri dishes, the presence of both silver and aluminum-bronze wire seems to check the growth of bacteria. This is also noted in the human body, when aluminum-bronze wire is used for sutures. It is as good as silver wire and much less expensive. Pichler recommends it, especially where infection of the stitches, from the skin down, is to be feared; in hernia operations; in plastic operations on the lip; in fact, wherever tension is exerted, or the stitches are to be left in place for a long time. [M. O.]

April 27, 1901. (28 Jahrgang, No. 17).

1. Atropin before Administering Ether. LUDWIG BRAUN.

Braun has etherized 100 times in the past year, in Dr. Fuerth's Sanatorium in Vienna, using Merck's ether, and the Longard-Wagner mask. He says that no more mucus collects during anesthesia than when chloroform is used.

The patients seemed to be quietly sleeping. In only two cases did pneumonia follow, and both of them had been operated before. In giving ether, he always gives a few drops of chloroform first. Subcutaneous injections of morphin were only given three times. Braun considers atropin needless before operation, more especially as it is a dangerous drug. [M. O.]

CENTRALBLATT FUER INNERE MEDIZIN.

April 6, 1901.

- Concerning the Gualacol Treatment of Acute Gonorrheal Epididymitis. BERTHOLD GOLDBERG.

The article is chiefly a review of the literature concerning the treatment recommended by the author; this leads him to the conclusion that the treatment has not been so widely used as it deserves, and that it is the best local treatment that can be advised, and leads almost without exception to satisfactory results. He has seen no unfavorable influences from the treatment. [D. D. E.]

THE JOURNAL OF NERVOUS AND MENTAL DISEASES.

April, 1901. (Vol. No. 4).

1. The Clinical Value of Astereognosis, and its Bearing upon Cerebral Localization. G. L. WALTON and W. E. PAUL.
2. The Babinski Reflex. C. VAN EPPS.

1.—Walton and Paul state that in hysteria the character of the astereognosis as well as the distribution of anesthesia and its completeness will generally indicate the nature of the disease. For example, a patient in whom a pinch or prick is not noticed and no object is recognized when the stereognostic sense is tested, will handle objects naturally and freely with the affected hand. It has been found that patients suffering from cerebral anesthesia have the stereognostic sense lacking. Cerebral anesthesia of the astereognostic type occurs in both cortical and cerebral disease, between which we are unable to distinguish by this symptom alone. The author thinks that the ability to recognize objects held in the hand with the eyes closed is a matter not of any one simple sensation, but a complex judgment based on correlated memories of various forms of contact sense, spacing, localizing, pressure, together with the so-called muscle sense. It is in cortical or sub-cortical disease that astereognosis is likely to prove of material diagnostic assistance. [T. M. T.]

2.—Epps found that in 68 hemiplegics the Babinski reflex was present. Extension of all the toes, big toe most, 50%; extension of the big toe, small toes flexed, 27%; extension of big toe, no mention of small toes, 22%; extension of small toes only, 1%; extension of all toes, small toes most, 0%. In examining 500 cases he found normal plantar reflex absent on both sides in 19 cases, or 3.8%; absent on one side, 11 cases, or 2.2%. In children, he found the extension, usually of all toes in 50%; flexion, usually of all toes, 20%; irregular flexion and extension, 20%; feet held too stiffly to obtain reflex, 8%; absence of motion, 2%. Out of 213 cases of nervous disease with no manifest disorder of pyramidal tracts, including tabes dorsalis, Friedreich's ataxia, paralysis agitans, progressive muscular atrophy, multiple neuritis, etc., flexion was present in 167 cases, or 78%; no motion in 38 cases, or 18%; constant extension of both feet, 5 cases; in one foot, 1 case; and in two cases irregular flexion and extension in both feet. In hemiplegics and diplegics, of which 118 were examined, extension was present on the paralyzed side in 57%; flexion of all toes in 26%; flexion of the small toes only, 4%; irregular flexion and extension, 5%; no motion, 8%. On opposite side extension was present in 9%; flexion of all the toes, 72%; flexion of the small toes, no motion in big toe, 4%; irregular flexion and extension, 5%; no motion in 10%. In plantar reflex in spinal cord disease with lateral tract involvement, out of 62 cases, extension was present in 63%; flexion in 26%; no motion in 11%. [T. M. T.]

Special Article.

THE EYE AND EAR EXAMINATIONS
OF RAILROAD EMPLOYEES.An Echo From the St. Paul Meeting of the American
Medical Association.By WILLIAM THOMSON, M. D.,
of Philadelphia.Emeritus Professor of Ophthalmology in Jefferson Medical College,
Philadelphia.

At the annual meeting in 1900 at Atlantic City, the writer was added to the Committee on Visual and Aural Qualifications of Transportation Employees, of which Dr. Allport was Chairman.

Shortly before the St. Paul meeting the proposed report of the Committee was submitted to me for my action.

After an experience of over twenty years in agitating the questions involved, I deemed it my duty to our Section to hold out the danger signal, and avert a collision with the officers of the railroads, well knowing what the results would be of any attempt to intrude opinions that would seem to conflict with the rights of railroad officers to manage their business themselves. My views were embodied in a minority report which was sent by mail, in good time, to the Secretary of the Section on Ophthalmology, with a request that it be presented in the debate. After the meeting the Secretary reported that no such letter had reached him. The postal service finally delivered it to him at his home in Memphis, and by him it was sent to the Editor of the Journal of the American Medical Association for publication with the proceedings. A request for its appearance in print from the writer was answered by the Editor in the negative, after consultation with one member of the Executive Committee, on the ground that it had not been presented to the Section. A note from the Chairman of the Committee, and now Chairman of the Section, also claimed that, his report having been unanimously adopted, this had "closed" the incident; and he hoped that it might not be reopened.

From no fault of the writer he is deprived of the chance of discharging his duty to his colleagues, and is hence compelled to offer his opinion to the profession in this manner, or remain a silent supporter of views which he has for years opposed.

Dr. Allport's report must now be read, and will be found in the *Journal* for June 22, 1901, p. 1795. It demands that the work of testing the sight and hearing of railroad employees "must be superintended by this Section," and must be made by eye and ear surgeons, etc.; and in his pamphlet he, in italics, expresses his opinion that it were better if "such examinations were never made by non-professional men."

Having persuaded the officers of the Pennsylvania Railroad, more than twenty years ago, to protect themselves and the public, in conjunction with their most intelligent Division Superintendents and the writer, a system of examination by educated and instructed non-professional examiners was put in force. Slowly it gained the confidence of other

railroad officers, and was adopted by various other corporations estimated in 1900 to amount to 111 in number and controlling 150,000 miles of road, an increase since 1894 of 100,000 miles.

The system demands the supervision on each road of skillful ophthalmic surgeons to see that the tests and examinations are properly made; and these trained observers are the men best fitted to give advice to our Section.

We have on one side those who believe that no layman can be trusted to use the refined instruments required; and, on the other, the highest experts, like Eldredge-Green, in his recent paper in the *Lancet*, on the Shortcomings of Holmgren's Test, stating that even Mr. Nettleship, famous as surgeon and writer, had failed to detect a color-blind man by wool tests.

With such burning differences of opinion, it becomes prudent men to be careful in promoting discord which will at least hold up any further peaceful evolution of the extension of scientific supervision of optical defects to the entire railway system of the country.

This minority report is so mild that one may wonder why it should be so hindered in its effort to appear. With this discharge of duty to my colleagues of the Section, the writer deems the matter now "closed." The following is the report:

MINORITY REPORT.

Mr. Chairman and Members of the Section of Ophthalmology of the American Medical Association.—

I may be unable to be present at our meeting at St. Paul to discharge the duty laid upon me at our last meeting to aid in advising the Section what action to take upon the report of the Committee on "The Visual and Aural Qualifications of Transportation Employees," of which I am a member, and Dr. Allport is the Chairman.

The substance of a report has been submitted to me by the Chairman, and in my inability to confer with the Committee, and other colleagues, I feel constrained to object to its wholesale condemnation of examinations made by instructed but non-professional persons; and to the demand that they should be made by none other than ophthalmic and aural surgeons.

It is well known that twenty years ago the Pennsylvania Railroad adopted, and has kept in use since, amended and improved, a system of non-professional examinations, and that it has been adopted by other corporations estimated to control about 150,000 miles of track.

Our Section might well pause before the task of overthrowing so useful a beginning, instead of trying to improve it by further evolution. In such an issue some members of our Section might be brought into antagonism with the officials of great roads of which of which they are now valued advisers.

We possess little or no power, except that of persuasion, to enforce any changes we might demand.

The officers of roads having now any system would hesitate, in the present condition of the labor market to invite struggles with their employees by re-opening questions so full of danger.

It must also be remembered that the well-described dangers from defects of color and form no longer exist, except on those roads which have never adopted any system. On the P. R. R. the dangerous men were eliminated twenty years ago, and the system now suffices to prevent their admission. So well satisfied are the officials of that road—controlling 15,000 miles of track and 120,000 employees—that no influence of mine would suffice to overthrow their confidence in it; and I shall remain content with the system when my recently improved lantern has been adopted generally as an addition to the color stick and wools, since it will detect those doubtful cases of green-red blindness which have caused distrust in the Holmgren method so well described by Eldredge-Green in the April number of the London *Lancet*.

The ophthalmic surgeons of our great roads are best fitted by their experience and influence with the officials of those roads to guide us aright, and I would suggest that the present Committee be increased by the addition to it of a sufficient number of them to decide as to the possibility of pressing upon the roads the necessity of using only specialists as examiners; the division of employees into classes; and the consequent frequent re-examination of all signal men.

I will conclude by adding an extract from a letter of May 3rd, from the General Manager of the Pennsylvania Railroad:

"I am in receipt of papers sent by you, and desire to say that, so far as our system East of Pittsburg and Erie is concerned, we have no desire to change the method inaugurated by you for the examination of employees in connection with color sense and acuity of vision. The method has been entirely satisfactory, and with such improvements as you have made and are making we are entirely satisfied.

"In order to ascertain the views of our Western Lines upon the same subject, I asked their General Manager for his views, and he advises me that the present method of examining employees for color sense and acuity of vision, as prescribed for by you, has been found entirely satisfactory on his lines. He received copies of pamphlets issued by Dr. Allport, of Chicago, and had them gone over by the oculist of his company, and it was recommended by him that they make some slight changes in their practice; the changes, however, being minor ones, and not affecting the principle of their present practice."

An experienced Division Superintendent also writes me:

"So far as Dr. Allport's attitude is concerned to the arrangement in existence on the Pennsylvania Railroad, for examination of employees, I would say that I do not think you will get any of our operating officers to agree that our present plan is not effective. Personally, I prefer it to any other that has thus far been suggested. It is a clean, concise, and definite way of ascertaining the condition of a man's sight and hearing, and I prefer it to taking the judgment of those who are interested solely in making the examination. I believe I have on one occasion told you that one of the greatest advantages of our present method of examination is that we, as examiners, have no interest in any particular

employee, and our sole object of examination is that we may not place employees in positions in the service that would jeopardize life or limb."

"I am unalterably opposed to local surgeons having charge of this work. The layman can secure as effective results with your apparatus as the surgeon, and there is no probability of the layman being influenced to give anything but actual facts—in fact, he must, or make himself a party to the complications that would arise in employing those unable to pass the examination properly.

"Our present methods keep 'politics' out of the transaction. We need no professional assistance other than that which you are this week giving my train-masters."

Respectfully submitted,

WM. THOMPSON, M. D.

The Treatment of Otitis Media and its Complications.—W. A. Niemtschenko (Bolshechnaia Gazeta Botkina, Vol. XII, Nos. 10-11) treats this very obstinate and almost incurable affection in the following manner: In mild cases he employs a 2% solution of phenol in 50% alcohol. Of this solution 10-15 drops are placed into the auditory canal, while the patient's head is inclined toward the healthy side, and by means of a small pledget of cotton the walls of the canal are rubbed energetically so as to bring the solution in intimate contact with every portion of the canal. The solution is allowed to remain for 2-3 minutes, when the patient inclines the head towards the diseased ear to permit the exit of the fluid. This solution answers a two-fold purpose: In the first place, it dissolves out the fatty material coating the walls of the canal, permitting the medication to come in direct contact with the inflamed tissues, and second, it acts as an antiseptic. The applications are made daily at first and at greater intervals as the suppuration diminishes. When marked improvement takes place, the applications are discontinued, for the reason that the antiseptic is liable to injure the new-forming tissue. Many cases of otorrhea of long standing were cured by this treatment. In the graver forms of the disease, especially those accompanied by an elevation of temperature or meningeal complications, the author injects a 5% solution of carbolic acid into the surrounding tissues of the middle ear, in the following manner: The auricle is pulled forward so as to put the retrahens muscle on a stretch; the needle is inserted into the squamosmastoid fissure and carried along the cartilaginous wall of the external auditory canal until it reaches the middle ear, and a syringeful of the solution injected. The solution acts not only as an excellent antiseptic but is also an anesthetic, the patient experiencing almost immediate relief. Following the injection, the exudate soon becomes serous in character and disappears entirely on the 12th day. However, should the disease be still lingering, the injection is repeated. The recovery is usually so rapid that in no case did the author have to resort to more than three injections. This treatment was employed in 36 cases (9 acute and 27 chronic) with uniformly good results. [A. R.]

Cesarean Section on a Girl Thirteen Years Old.—The pelvic measurements of the girl were: Interspinous, 19.5; intereristal, 24; external conjugate of Baudelocque, 16; diagonal conjugate, 11; vertical height of symphysis, 4.5; conjugata vera of brim, 9.2 centimeters. The vagina was so small that the introduction of two fingers caused pain. The patient was found bleeding profusely from the vagina, the amniotic fluid had escaped, the umbilical cord was prolapsed into the vagina and the os was dilated to the size of a dollar and filled with blood clots. The hemorrhage being alarming, the vagina was packed and Cesarean section done. The fetus lay transversely and the placenta was attached posteriorly, one-fourth being in the lower segment. The case was notable because of the fact that conception took place at 12. The fetus was well developed and had entered upon the ninth month. Patient recovered without incident.—*American Journal of Obstetrics*.

DYSTOCIA FROM COILING OR OCCLUSION OF THE
UMBILICAL CORD.

By EDWARD P. DAVIS, A. M., M. D.,

of Philadelphia.

Professor of Obstetrics in the Jefferson Medical College, Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic, Visiting Obstetrician to the Jefferson, Philadelphia and Polyclinic Hospitals, etc.

A complication which may prove fatal to the child and considerably interfere with the mother's labor is coiling or occlusion of the umbilical cord. Where the cord is excessively long and the fetus active, the child may coil the cord about the neck several times, over the shoulder and under the axilla or pass it between the lower limbs. Upon the occurrence of labor, tension upon the cord interferes with the passage of blood, asphyxia develops, and the fetus is threatened with death. In rare cases, the cord may be so tightly coiled as to amputate a limb before labor occurs.

The diagnosis in this condition is made by recognizing a murmur or souffle in the cord. Clinical observation appreciates altered movements in the fetus, and the mother may report fetal movements more slow and feeble or for a short time excessively strong. In some cases the movements become so feeble that the mother fears that the child is dead.

While the danger in this condition is primarily to the child, the mother may also suffer. Partial separation of the placenta has resulted from traction upon the cord during labor, and in some cases inversion of the uterus is thought to have been favored by this complication.

Rupture of the cord is occasionally observed in cases in which the mother is delivered while standing, the child falling upon the floor. Rupture of the cord does not happen during birth in the recumbent posture, although the cord may be tightly drawn about the child.

This complication is of sufficient importance to call for recognition and for prompt interference during labor in the interests of the child and of the mother. The following cases illustrate the points in question:

CASE 1st.—A young primipara came into labor with the child in the first position, vertex presentation. Upon auscultation the heart sounds could be distinctly heard in the usual location. Between two and three inches below this point and toward the median line was heard a short, sharp hissing murmur, slower than the fetal heart sound and quicker than the uterine or placental bruit. The fetal movements were not excessively vigorous, labor proceeded slowly, the fetal heart sounds remaining strong and slow. The child was evidently of good size, and in view of the condition of the cord and the danger of asphyxia, it was thought best to interfere so soon as the head had descended into the pelvic cavity. The patient's husband was informed of the complication and that it might prove fatal to the child.

So soon as the head descended upon the pelvic floor, the heart sounds remaining good, the child was delivered by forceps. The cord was found coiled three times about the neck, passing over the shoulder across the body underneath the axilla of the opposite side. The child was asphyxiated, but was revived without especial difficulty.

CASE 2nd was that of a multipara, whose pregnancy proceeded normally until the usual limit. She summoned her physician, stating that she had been suffering for a day with nagging labor pains without progress, and that the child's movements had grown slow and feeble.

On examination, no murmur could be heard which could be ascribed to the cord, the heart sounds were slow but distinct and strong. Labor occurred within a few hours of the time when the physician was summoned, and spontaneous expulsion resulted. The cord was wrapped about the neck over the shoulder and beneath the opposite axilla. The child was asphyxiated, but readily resuscitated. In this case, the condition was recognized so soon as the head came down upon the pelvic floor, and it was possible to loosen somewhat the upper turn of the cord and thus prevent its complete occlusion.

It is evident that the conditions prevailing when the cord is coiled about the fetus are different from those in cases where the cord is short without coiling or where it is occluded by prolapse or by amniotic adhesion. If the cord be coiled and the child be so low in the birth canal that it can be delivered with forceps, there is always the probability that the cord may be stretched sufficiently to allow the head to escape without separating the placenta. If the cord were short without coiling, the child could not be rapidly delivered without separating the placenta or injuring the cord very materially. In distinguishing between the two, the cord murmur is valuable. A short uncoiled cord gives rise to no murmur, while a normal cord coiled about the fetus produces the murmur described.

If the head be expelled with the cord coiled about the neck, and the cord be drawn so tightly that further expulsive effort on the part of the mother ceases, the cord should be clamped by two hemostatic forceps and cut between. In such cases, the cord is drawn so tightly that it is impossible to loosen it and slip it over the child's head.

The writer was called in consultation to a tedious labor and entered the patient's room just as the head of the child was born. The cord was tightly coiled about the neck and stretched to the utmost, and expulsive efforts failed to deliver the shoulders. The cord was immediately clamped and cut when the child was delivered and resuscitated. Here very prompt action was necessary to save the life of the child.

Prolapse of the cord often occurs in contracted pelves, in transverse presentation, and in cases where the descent of the fetus is prevented by deformity or the presence of tumors. The indication is to replace the cord as soon as possible and to deliver the patient as readily as is consistent with safety.

To replace the prolapsed cord, the knee-chest or lateral posture, the introduction of the hand, the carrying of the cord above the brim of the pelvis, followed by the performance of podalic version form the most effective method of treatment. Anesthesia, partial or complete, is usually necessary. The advantage of introducing the hand is not only to perform a satisfactory version, but also because it enables the operator to make a complete and accurate diagnosis of the condition present. Pelvic deformity, the presence of a tumor, or an abnormal condition of the child can be detected by this means.

In cases where it is impossible to introduce the hand, an attempt may be made to replace the cord by Braun's repositor or by a catheter stiffened by a stylet. A loop of sterile twine is passed through the catheter and out at the eye, then about the cord and the loop is caught over the tip of the catheter and pulled snugly down upon the cord. With the patient on the back or in the knee-chest posture,

the catheter is gently introduced, carrying the cord above the brim of the pelvis. The posterior extremity of one of the oblique diameters of the pelvis should be selected for this manipulation. When the cord has been introduced, the twine is loosened, the catheter withdrawn, when the loop of twine slips over the tip of the catheter, thus releasing the umbilical cord. Should it be impossible to replace the cord, the patient should be delivered, and if labor be delayed, she may be placed upon her side with the pelvis elevated.

Remarkable success sometimes attends the attempt to save the life of the child, although the prolapsed cord is without pulsation. If the cord can be carried above the pelvic brim and left absolutely free from pressure, circulation is sometimes established in apparently hopeless cases.

Knots in the umbilical cord may be fatal to the fetus by occlusion. In some cases, their formation is preceded by very active fetal movements recognized by the mother. In others, the mother may complain of pain and sensitiveness in the uterine wall with gradual cessation of fetal movements. Weston¹ reports two cases occurring in the last months of first pregnancies. In one case, the patient stooped to lift a heavy object and felt unusual motions within the abdomen, which soon ceased. In the second case, the patient's first symptom was nausea, which occurred at night. This was followed by unusual sensations in the abdomen with failure of fetal movements. The case was one of twins, and one child had passed through a loop in its cord, tying a knot about the other cord and stopping the circulation in both.

Occlusion of the umbilical cord by bridles or adhesions of the amnion is sometimes observed. Couvelaire² reports the case of a multipara in labor in whom no fetal heart sounds could be heard. The fetus was dead when born, but not macerated, and had evidently perished not long before delivery. Upon examination, the cord was large and edematous and 20 cm. from the placenta, strangulation had been produced by a bridle of amniotic membrane. The lumen of the cord was reduced to 7 millim. at that point.

A short cord may also result in the death of the fetus or the separation of the placenta. Brickner³ describes the case of a primigravida with no history of illness or accident. The patient's labor was tedious and her pains infrequent and weak. When the cervix was almost dilated the membranes were ruptured in the hope that labor would proceed. The head finally came upon the pelvic floor and could be seen at the vulva, but was retracted as soon as uterine contractions ceased. In the intervals between the pains, bright blood escaped in small quantity. The patient complained of pain over the left side of the uterus and voided urine freely between the pains. The child was asphyxiated, but resuscitated. The placenta was easily and quickly removed and was found to have been separated for some time and covered by a large and thick clot. The cord measured $10\frac{1}{2}$ inches in length. The child had an umbilical hernia from which it recovered without operation. Attention is drawn to the bleeding which occurred, and urination between the pains as symptoms of this condition. The recession of the head, pain over the placenta site, inertia of the ute-

rus and the patient's desire to sit up are also symptoms noticed in these cases.

In seeking indications for treatment in these cases, our experience and observation have led us to conclude as follows: The situation of the placenta should be ascertained as nearly as possible before labor in each pregnant woman. A study of the fetal heart sound, the placenta bruit, the uterine bruit and the beating of the mother's aorta will enable the physician to recognize a murmur in the umbilical cord. If this can be plainly distinguished, it is excellent evidence that the cord is coiled about the child. In the absence of a murmur, tedious labor in which no other cause for delay can be assigned, recession of the presenting part between the pains, ceasing or slowing of fetal movements, and the sensation of pain referred to the body of the uterus form strong presumptive evidence that the cord is coiled about the fetus. In cases of coiling, the patient should be delivered as soon as possible and the use of forceps is justifiable.

Where, however, the cord murmur is absent, but recession of the presenting part, arterial hemorrhage between the pains, pain in the uterus, uterine inertia and delayed labor are present, a cord anatomically or practically shortened is present. In such a case, the use of forceps is not indicated.

The patient's labor pains should be stimulated, her strength maintained, the child delivered so soon as the head is born, and the placenta removed as soon as possible.

In knots or occlusion of the cord by amniotic adhesions, nothing can be done to save the life of the fetus. In the interests of the mother, the uterus should be made to expel its contents so soon as fetal death is positively diagnosed.

EMPHYEMA OF THE FRONTAL AND ETHMOIDAL SINUSES AND ORBITAL ABSCESS.*

By THOMAS R. POOLEY, M. D.,

of New York City.

The following case seems to me worthy of record, for divers reasons, which I will enumerate and dwell upon to some extent after reporting its history and the operation done for its radical cure:

The patient, a young gentleman of 19, was admitted to my hospital March 25th, at 5 P. M., suffering the most intense pain in and around the right eye and over the entire side of the head.

The eyelids both upper and lower were enormously swollen, red, and shiny, so that they could hardly be opened to inspect the eye, especially as they were exquisitely sensitive to the touch. Inspecting it, however, there was found to be some chemosis, most prominent at upper inner angle—slight ptosis and some restrictions of the movements of the eyeball inwards and upwards. In the upper inner angle just above the insertion of the tendon oculi was a minute fistulous opening, but there was no discharge from it.

*Read before the American Laryngological, Rhinological and Otological Society, in New York, May, 1901.

His temperature was 104 F. and pulse 120° and there seemed to be some mental disturbance, which, however, might be due to the narcotics he had taken to relieve the intense pain. The following history was obtained from his mother's statement.

Ever since he had scarlet fever, six or seven years ago, this eye has been affected, being at times painful and watery, but no severe trouble occurred until six years ago, when while staying in Boston he felt his eye uncomfortable, and by the time he reached home the lids had swollen a little. A diagnosis of erysipelas was made and hot applications applied. He was treated by several physicians, but there was no improvement.

Dr. O. F. Wadsworth was called in consultation and made an incision below the margin of the lower lid. This caused subsidence in the swelling of the lids to a minimum extent, but some pain and swelling still remained. Four years ago he was operated upon in the Massachusetts Eye and Ear Infirmary by Drs. Standish and Jack. This operation, which seems only to have been evacuating the contents of the swollen sinus, was followed by temporary relief, the swelling remained in the inner angle, and a permanent fistula. For about a year past he had suffered very little inconvenience until the present trouble. A few days before I saw him he was treated by Dr. Coe who referred him to me.

Taking into consideration the antecedent history, in conjunction with the present condition, I was led to make the following diagnosis. Chronic empyema of ethmoidal and frontal sinuses, acute exacerbation and abscess of the orbit. For immediate relief of the patient's pain, I made with a Graefe's knife an incision into the fistulous opening, but no pus escaped, nor did it do any good. The following day, with the assistance of Drs. Myles, Spence, and Cook, the house surgeon, I proceeded to operate, the patient being fully under ether; the skin shaved and the region of the wound washed with green soap, then with ether, and bichloride 1-5000.

An incision was made beginning at the outer third of the orbital ridge to the internal canthus, thence downwards and inwards along the nose to the lower border of the orbit, carefully avoiding the superior oblique muscle. The dissection was made close to the bone, the periosteum reflected fully exposing the upper and inner surfaces of the orbit. An examination showed a fistulous opening in the anterior wall of the frontal sinus through which a probe could be passed into its cavity. The frontal sinus thus discovered was enlarged by means of chisel and gouge so as to admit free access thereto, and was found to be filled with polypoid granulations which were thoroughly removed by means of a sharp spoon. The sinus seemed to be dilated much beyond its usual size. The ethmoidal cells were then explored and found to be soft and infiltrated with pus. The incision was then carefully carried along the inner wall of the orbit and an exploration of the cavity made. It was done partly by dissection with a scalpel, using mainly the handle thereof. Upon entering the depth of the orbit a large cavity of pus equal to one or two drams suddenly escaped. The opening was made through the anterior ethmoidal cells into the naso-frontal canal and the infundibulum and down through the nose. On the end of the probe was an eyelet through which a thread was passed, attached to a soft rubber catheter which was then drawn through, carrying the tube with it, one end coming through the opening in the sinus, the other through the nose. The ends of the tube were tied together to keep it in place. The cavity and antrum were packed with strips of iodoform gauze. The wound was carefully packed around the tube and five sutures taken in the wound, over this a wad of absorbent cotton, and the whole held in place by a firm roller bandage.

Immediately following the operation there was subsidence of the swelling of the eyelids and the following day the temperature was normal.

During his stay in the hospital, about three weeks, after the operation, there was a continued and uninterrupted progress toward recovery. The wound was dressed twice daily after irrigation being made into the opening in the frontal sinus, and through the drainage tube into the nose, there being used at different times therefor saturated solutions of borie acid and normal salt solution and occasionally a 1/10,000 solution of bichloride.

The first drainage tube introduced was allowed to remain in position for about two weeks, it was then removed and

a Myles frontal sinus drainage tube introduced in its place, to which was attached at its upper extremity a thread which came out the wound, and to the lower another which came out through the inferior meatus of the nose. This tube with which you are no doubt familiar, has a flange at its upper extremity which projects from the opening into the wound and is introduced into the nose about as far as the superior or middle nasal meatus.

At the time of his discharge from the hospital, the wound with the exception of the point where the drainage tube entered, had healed by primary union. An examination of the nose made at this time by Dr. Myles, showed a large number of nasal polyp. After his discharge from the hospital the patient came daily to my office in order to have his wound dressed, which dressing consisted in packing the frontal sinus first with iodoform and afterwards with sterile gauze, and in irrigation through the nose and drainage tube. This was continued for about four weeks, at the end of which time the drainage tube was removed through the nose, and for some time after its removal irrigation of both the frontal sinus and nose were continued until at the expiration of about two months after the operation the wound had entirely healed.

An examination of the nose made just before he discontinued treatment showed that the nasal polyp had entirely disappeared.

At this time as you will see by looking at the patient, there remains some edema of the upper lid and a slight scar which is somewhat drawn inward at the inner angle. The patient is now quite free from inconvenience or trouble of any kind and has returned to his usual avocation.

The feature in this case, which is the most interesting and worthy of comment, is the sudden invasion of an acute exacerbation upon a chronic sinusitis of both the frontal and ethmoidal sinuses with severe constitutional symptoms, i. e., intense swelling of the lids, chemosis, protrusion of the globe and restricted movements of the eye ball, clearly pointing to the presence of an abscess in the orbital cavity. This no doubt was superinduced by an extension of the inflammatory process which began in the one or both sinuses, extending into the orbital cavity, and which was clearly diagnosed before the operative procedure was begun, and rendered immediate surgical interference imperative.

Another interesting point to which I wish to call your attention is the apparent connection in the affection of one or both sinuses with scarlet fever, in the paper which I read before the Eastern Section of this Society, in Philadelphia, February 17th, 1900. I reported a case of necrosis and empyema of the frontal sinus, which was also attributable to this cause. The patient had been otherwise in good health until the age of 16 years, when he had an attack of influenza, followed in two weeks by scarlet fever, resulting in the development of an abscess in the orbital region associated with considerable orbital cellulitis. I mention these two cases in connection because of the apparently causal relation existing between this exanthema and affections involving both the orbit and the accessory sinuses. This is, perhaps, not to be wondered at when one considers the inflammation of the mucous membrane of the throat and nose so characteristic of this disease.

In the case which we are now considering, it was the neglect, or rather inefficient treatment of the chronic process, which resulted in the severe acute symptoms which ensued when the patient came under my notice, and suggests the necessity for a more radical operative procedure in all cases where the inflammatory process manifests itself by external swelling in the upper inner angle of the eye, with

tenderness and swelling of the lids, which is a sure indication of an empyema of the ethmoidal and probably of an implication of the frontal sinuses as well.

The mere opening of such swelling and evacuation of pus can only give temporary relief, and permanent relief is only to be obtained by an operation which will permit of a free exposure and thorough exploration of the condition of the frontal and ethmoidal sinuses and the establishment of free drainage through the nose.

Without such interference a fistula may exist, as it did in this case for years, and brain complications may ensue at any time.

Upon the different methods of operating to accomplish this result, I have dwelt more at length in the paper to which I have already referred (loc. cit.).

A very interesting fact in this case to which I wish to call your attention is the complete and entire disappearance of the numerous nasal polypi after the operation, which goes to show what I think has been pointed out before, that the appearance of these polypi is dependent upon disease of the ethmoidal cells. The specially interesting and intimate connection existing between the disease of the nasal sinuses and the ocular affections, has attracted the attention of both oculists and rhinologists, and it would, perhaps, be difficult to add anything new in this particular. Cases of both frontal and ethmoidal disease of the sinus nearly always exhibit some ocular manifestations, but it is particularly those cases with the involvement of this organ which come under the care of the ophthalmologist. I have observed cases in which neuritis and subsequent atrophy of the optic nerve, have been the result of such processes by an extension of the infection along the sheath of the optic nerve.

An interesting article bearing upon this question has been recently published by Broeckart (*Revue Hebdomadaire de Laryn. et de Rhin.*, Jan. 5th, 1901). In this article he enumerates a number of ocular complications, sometimes only slight, passing troubles, sometimes serious, very often grave complications, such as inflammation of the orbit, paralysis of the muscles, narrowing of the visual field, atrophy of the papilla, iridocyclitis, panophthalmitis. These conditions have been the object of numerous studies, and I do not intend here to dwell upon them as they are enumerated in the article to which I have referred, and which are easily explained on the ground of the close proximity of the eye and the sinus, as in this case it is easy to conceive that affections of the anterior ethmoidal cells may easily extend to the orbit, since ethmoidal sinusitis is almost always accompanied by frontal sinusitis. We all know, too, how often disease of the nose and adjacent cavities may react upon the eye by the nervous route, the trigeminal and cause phenomena which are purely reflex. As is shown by the author, I have already quoted, even iritis and opacities of the vitreous and retinal detachment follow in the wake of these affections. Without any attempt to more than merely suggest by these brief enumerations the dangers which may result by extension of the diseases of these accessory sinuses to the organ of vision. I leave the matter for your further study and observation.

In conclusion, I wish to express my sense of obligation to Dr. Myles for his most able assistance and valuable suggestion which contributed so much to my success in this case.

SPINAL ANESTHESIA.*

By ANGUS McLEAN, M. D.,

of Detroit, Michigan.

Attending Surgeon, Harper Hospital; Clinical Professor of Surgery, Detroit College of Medicine.

This subject has been very prominent in the minds of many surgeons for the past ten months. It has, also, been discussed freely in the leading medical journals of the world and is still a subject of active interest. Like all new themes, it has its enthusiastic supporters as well as those who criticize its administration. I believe that it will maintain a useful position in the field of surgery, but just what the boundaries of its uses are has not yet been decided.

The domain of cocain as an analgesic is gradually increasing. First, it was used as a local external application on mucous membranes; secondly, a few minims of the stronger solutions were used subcutaneously to a limited area; thirdly, it was used in a diluted solution, combined with morphine and salt (Schleich's formula) to extensive areas; fourthly, it was injected into nerve trunks; fifthly, it has been introduced directly into the spinal canal, that it might have a direct action on the lower portion of the spinal cord. It is to its use in the latter position that we will confine our remarks in this paper.

Spinal Cocainization is an American idea. Attention was first called to it by Dr. Leonard Corning, in his experimental work, as early as 1885. Prof. Bier, of Germany, took it up about two years ago and did some work with it. This was followed by Prof. Tuffier, of Paris, who demonstrated its applicability in all operations below the diaphragm. Since August, 1900, it has been used in all the medical centres of this country. Its application consists of injecting into the lumbar region of the spinal canal an aqueous solution, containing from 1-5 to 1-3 of a grain of cocain hydrochlorate, preferably a two per cent. solution. Many needles have been devised for this purpose. Some are made of platinum and gold and are quite expensive. I have always used a needle of finely drawn crucible steel, with a trocar inserted, that I have made by the J. F. Hartz Co., Detroit. It is an inexpensive needle, and has always proven very satisfactory. The all-glass syringe and the glass syringe with rubber-tipped piston are the most satisfactory, for they can be sterilized by boiling. They are, also, inexpensive, and can be discarded after use if desired. The needle is inserted through the lamellar space of the fourth and fifth lumbar vertebræ. This is the usual space, though a space or two above will answer. The tip of the spinous process of the fourth lumbar vertebra is taken as a guide. This is on a level with the crests of the ilia. The patient is in a sitting posture with the spine well flexed. The needle is inserted about one-third of an inch from the spinous tip (laterally) and directed inwards and to-

*Read before the Surgical Section, Michigan State Medical Society, held at Battle Creek, Mich., May 15th and 16th.

ward the medium line until it enters the spinal canal. If the needle is in the proper position the spinal fluid will flow through it when the trocar is withdrawn; this is evidence of its being in the canal. This was thought necessary at first, but some surgeons have succeeded in producing analgesia without entering the canal; simply injecting it outside the subarachnoid membrane, absorption taking place through the membrane. The cocain may be prepared in different ways: By dry sterilization in small envelopes and dissolved in the proper amount of sterilized water, when required; by means of the water bath, or by filtration through a Chamberlain filter. By careful sterilization of the needle, syringe and solution I do not think there is much danger of infection. I have not seen nor heard of any cases of sepsis following its introduction. The injection affects patients differently. Some will succumb to its analgesic effects in from eight to twenty minutes, while it will take from twenty-five to thirty minutes to produce the same symptoms in others. Analgesia begins in the soles of the feet and extends upwards to the umbilicus and as high as the clavicle. I do not know just why this difference should be, but have thought it might be due to the location of the cocain in the canal, or to the amount of cerebro-spinal fluid present. It not only differs in its analgesic properties, but it produces general symptoms that differ greatly. Some patients will become pale and nauseated in a few minutes, and a little later will vomit. This may be accompanied by tremor of the lower extremities with the expression of a slight shock. Other patients will show no signs of gastric or circulatory disturbances or distress of any kind for the first few hours. They appear to be stimulated by its action and become quite talkative. The most constant and annoying distress that follows is that of headache, and this is frequently severe in the occipito-cervical region. It comes on from three to six hours after the injection and continues from twelve to eighteen hours, as a rule. In severe cases it may last three or four days. In one case I had it lasted for four days. It was confined to the occipito-cervical region and accompanied by rigidity of the muscles of that locality, which was not relieved by bromides, codiae, etc. Tropococain hydrochlorate does not produce the unpleasant after effects that cocain does. Willy Meyer (*Medical News*, April 15) reports using it in genito-urinary surgery with perfect satisfaction. Schwarz (*Centralblatt f. Chirurgie*, March 2, 1901) reports its use in sixteen cases successfully. The dose of this drug is from $\frac{1}{2}$ to 4-5 of a grain. I have used this preparation in two cases, but the analgesic effects were not satisfactory. It did not appear to produce complete anesthesia. Spinal narcosis was one of the subjects for discussion at the Thirtieth Congress of the German Surgical Association held in Berlin this year. At that meeting Mikulicz reported its use in forty cases with satisfactory results. He predicted that it would be one of the most important methods of anesthesia in the future, when it becomes perfectly understood. Bier, at the same meeting, had collected records of 1200 cases which had been operated on by this method. He pointed out that a great difference existed as to the amount of cocain required to produce the desired effects. The amount varied from one to three cgm. He has tried encain, tropo-

cocain, and other drugs, but these did not prove satisfactory. He stated that in many cases symptoms of cocain poisoning developed, such as nausea, dizziness, vomiting, chills, rise of temperature, circulatory disturbances, paresis, and in a few cases collapse and death had followed. He believes it requires further investigation before it is adopted in general.

In my experience the most annoying symptom that follows its use is the severe headache. This is somewhat relieved, however, by bromide, codiae, hyoscine hydrobromate, and nitro-glycerine. Just what this pain is due to has not been settled. Bier lays great stress on the point that the equilibrium of the spinal fluid be maintained, that is, that the same amount of cerebro-spinal fluid be allowed to escape that you intend to introduce of your cocain solution. I have seen severe headache follow when this precaution was closely adhered to. Prof. Laborde, of Paris, in experimenting upon animals, has shown that the injection of cocain produces two periods of intoxication. "In the first there is extreme hyperexcitability, the animal trembles, is agitated, and even has convulsions; the second period is analgesia without tactile anesthesia." He states that through the motion of the cerebro-spinal fluid the cocain may extend to the medulla, and believes it dangerous. Dr. Tuffier, its leading advocate in France, says: "Injection by this technique does not show imperfections." He continues his method and believes it to be harmless." Many obstetricians have used it in labor cases. They all report favorable results, and believe it a great advantage to the accoucheur. Intrarachidian injections of cocain are finding other fields of usefulness. It is being used as a therapeutic agent in sciatica. Dr. Archard has injected as much as three-tenths of a grain into the spinal column in cases of sciatica. Prof. Marie has been trying it in the same manner and reports great improvements from small doses introduced into the spinal canal. Judging from the above statements, it can be seen that the future limitations of lumbar puncture are still in doubt. For this method to supersede the use of general anesthesia it must be shown that it is less dangerous and distressing in its effects. That there are cases when it is indicated in preference to general anesthesia has been conceded. These are: when the patient is suffering from general peritonitis, distention of the stomach and intestines, disease of the kidneys, diseases of the lungs, and advanced disease of the heart.

I have operated by this method about twenty-five times, and I believe it is about as difficult to select the patient who will act favorably under its use as it is to select beforehand the patient who will act well under general anesthesia. I have seen the strongest men suffer most severely from its after effects. On the other hand, I operated on a feeble lady, aged seventy, for senile gangrene, amputating above the knee, and she did not suffer the slightest from the cocain; upon returning to her room, she immediately asked for a cup of tea and relished it; she sat up in bed during the day, as though nothing had happened. In the cases I have operated on there have been no symptoms of sepsis or spinal irritation following. I have recently seen some of those that were operated upon six months ago and they have no sequela whatever following.

As previously stated, I believe that lumbar puncture will have a useful position in the field of surgery, but I do not believe that the boundaries of its domain have yet been marked out. This cannot hope to supersede general anesthesia in all operations below the diaphragm until some method of technique or preparation of cocain has been selected that will be followed by less distressing after symptoms than we have from it as used at present.

REPORT OF A LIPOMA REMOVED FROM THE CHEEK UNDER MEDULLARY NARCOSIS.

By A. W. MORTON, A. B., M. D.,

of San Francisco, Cal.

Professor of Surgery and Clinical Surgery in the College of Physicians and Surgeons, Surgeon to the City and County Hospital.

This case is of unusual interest on account of the position and enormous size of the lipoma. It not only demonstrates that the cocain analgesia can extend over the entire body, but it tends to show the superiority of this form of analgesia over that of

ble from its weight and throbbing as well as its appearance. The patient has consulted a number of surgeons during the past five years, with a view to having it removed, but all objected to the operation, as his heart would not stand a general anesthetic. One surgeon sent him to a hospital and kept him under observation for three weeks and discharged him with the advice never to take an anesthetic.

It was only because of my belief in the safety of cocain that I decided to operate. Half an hour before the cocain injection the patient received $\frac{1}{4}$ gr. morphia and 1-30 gr. strychnia, hypodermically.

The injection was made in the second lumbar space, with the needle pointing upward, and twenty drops of a 2% solution of cocain were injected as rapidly as the piston of the syringe could be pressed. Analgesia was complete in the lower extremities in three minutes; to the fingers in ten minutes; over the head in twelve minutes. The tumor weighed nearly two pounds, after the blood was removed. I also removed the hemorrhoids by cautery. The patient was free from pain during the operation. He was slightly nauseated just before the operation. There was no emesis. The patient did not appear to suffer from shock and to all appearances was in much better condition at the close than at the beginning of the operation.

Figure 1. Lipoma of the Cheek.

a general anesthetic, especially in such cases as the following:

Mr. T., aged 65, clerk by occupation, height 5 ft. 8 in., weight 210 lbs., American born. He has had a lipoma of the left cheek of 25 years' standing; also internal and external hemorrhoids from childhood, varicose veins of the lower extremities, aortic insufficiency, enlarged, dilated, irregular heart and chronic nephritis; his urine was loaded with casts and albumen. His lower extremities were dropsical. The patient had been a constant drinker for the past fifteen years.

The tumor during the past year has caused much trou-

Figure II. After the Operation.

For days before the operation the pulse rate had varied from 100 to 120; at the time of the hypodermic injection, the pulse was 126; respiration 18. At the time of the cocain injection, the pulse was 128; respiration 22; fifteen minutes after injection, pulse rate 60; respiration 24; pulse rate was regular, full and not intermitting and varied during the operation from 60 to 64, which was normal and remained same after operation; respiration, deep and full, varied from 22 to 26. The patient took some whiskey during the operation and expressed himself as all right.

The wound closed by primary union, save at the center which closed by granulation.

THE RECOGNITION OF EARLY SYMPTOMS INDICATING DANGEROUS FORMS OF INSANITY.*

By W. K. WALKER, M. D.,

of Dixmont, Pa.,

First Assistant Physician to the Western Pennsylvania Hospital for the Insane

Of the many problems which confront the physician, none present such peculiar difficulties as that of mental alienation; determination of its existence involves decision upon a course of action which often profoundly influences the future prospects and the life of the patient. On the other hand, unwarranted delay in diagnosis may precipitate avoidable suffering or calamity upon the patient, his friends, or society. It becomes necessary to protect the patient, as well as society, from results of the essential and peculiar manifestations of his malady; the duties and responsibilities of the physician should therefore be as clear as in his dealings with other diseases which threaten the safety of the public. In a recent paper, Dr. Edward C. Runge admirably sums up the matter as follows: "In our times the sovereign state exercises its police power by enacting stringent health-laws, which have for their chief aim the protection of the many against the few who are considered a source of danger to their fellows. The threatened advent of cholera meets with rigid quarantine regulations at the seaports; millionaire and pauper alike are subjected to the same inconveniences for the sake of public safety. An outbreak of smallpox calls for immediate confinement of the victims in pest houses. Diphtheria and other infectious and contagious diseases cause the sufferers' isolation and the public stigmatization of his abiding place. There is an ever-growing tendency to deal with tuberculosis in an equally vigorous manner. In all these instances the common weal is considered paramount, the suffering individual having to submit patiently to inconvenience and possibly to considerable losses. With regard to the insane, the conditions are identical, for not a single case, be it ever so mild, is not to some degree harmful to some other unaffected members of society. The daily contact with an insane person, in families bearing so often the imprint of an hereditary predisposition, must exert a baneful influence on others about them."

Determination of the character and degree of mental alienation becomes a matter of importance as to the patient's being treated at home or whether commitment to a hospital is necessary; the latter is usually a measure of last resort through the feared disgrace or stigma attached to the admission of mental infirmity. With regard to those cases in which actual danger is threatened, however, there can be no difference of opinion, and early separation from home surroundings and isolation in a hospital especially intended for the care and treatment of the insane becomes imperative. Made to appreciate the existence of danger, relatives of the patient will usually be found quite willing to have the physician assume the weight of responsibility and to abide by his decision; though here, let me say, there may be need of all the weight and force of confidence in

diagnosis and conviction born of conscious knowledge which the physician can bring to bear.

There are difficulties in the way of dividing the insane into a harmless and a dangerous class, as there are in drawing within the narrow limits of definition a description of such a variable condition as insanity. Locke's oft-cited observation that "madmen do not appear to have lost the faculty of reasoning, but having joined together some ideas wrongly, they mistake them for truths, and they err, as men do that argue right from wrong principles,"² is to-day applicable to the majority of cases.

A practical advantage of definition is that it directs our attention to certain prominent features or complications attendant upon the disease, and one which I shall use, as serving the purpose of this paper is the following: "An insane person is one who is a menace to himself, to property, or to the peace and safety of others." From this view-point the psychic symptom is the essence of the disease, though we know it to be, in the great majority of cases, the outgrowth and final culmination of conditions and causes which have been operative for years.

Early diagnosis best enables us to control disease-processes wherever found; let us see whether there are indications by which we may early determine, as well, that danger is threatened to patient, property or others, that we may inaugurate proper precautionary measures, at the same time placing the patient under the most favorable conditions for the cure of his malady. We must first realize that morbid mental states (ideas, emotions, and even hallucinations and delusions), may exist unsuspected by those closely associated with the patient, though they may for a long time have been victims of his *bizarre* actions; this need not surprise us when of normal man it has been said that "no mind is wholly revealed to us. * * * No man is ever perfectly revealed to those who best know him. No man knows himself wholly. The higher the man the less can he be entirely acquainted with that self, the less can the world know him." (Weir Mitchell.)

It is a principle of normal psychology that we can interpret the consciousness of others only by their actions. Modern medical psychology reveals to us something of the mind of the psychopath according to this principle, and increasing knowledge of brain structure and function, with modifications due to disease, enables us not only to form conclusions with greater precision regarding the significance of such actions, but points the way to proper remedial measures. In addition, it explains the rationale of that plan of treatment systematized, and for so long a time successfully employed, by him who has in such large measure contributed to our knowledge of mind in its manifold morbid phenomena: To our reproach be it said that the French were the first to apply the broad principles of the Weir Mitchell rest cure to the treatment and management of the insane; and then we now extol, instead of its author, when dilating upon the advantages of "Séjour au lit,"—sojourn or rest in bed.

In hospitals for the insane we have the exaggerated forms of mental defectiveness; but careful study of these leads to clearer comprehension of the milder grades which often are never confined in

*Read before the Pittsburg Academy of Medicine, January 2, 1901.

hospitals, though they may constantly menace society. In general delirium with incoherence of speech, numerous and varied illusions and hallucinations, alternate weeping and laughing or intense maniacal furor: In melancholia with exaggerated sense of ill-being, profound emotional depression, and uncontrollable impulse toward suicide: Or in the patient presenting frightful hallucinations and delusions of persecution; who screams with terror or attempts suicide or homicide that he may escape from the horrors of the situation³—these present no difficulties in diagnosis, and it is but necessary to see them in order to decide what to do. Scarcely one patient in a hundred, however, presents this vivid picture; the majority, even when fully developed, often manifesting but slight deviation from the normal. In cases so obscure that we cannot feel sure of the existence of any of the cardinal symptoms of insanity, how may we justify a decision which, acted upon, so seriously affects the patient in deprivation of personal liberty, social standing and legal responsibilities?

In a general way, it may be said that just as we weigh and estimate the significance of symptoms representing known anatomical lesion, connecting disturbance of function with abnormality of structure, so we recognize causal relations between morbid psychic states and developmental, nutritional or structural change in the brain cell, with etiologic factors of heredity, neuropathic disposition, toxemias (metabolic and others), or extreme fatigue or exhaustion; we deal with clearly defined symptoms or symptom groups of disordered sensations, images, emotions and ideas, which form well-known types of mental disease progressing through a definite clinical course to partial or complete recovery, chronicity or death.⁴ In our psychological survey of the supposedly insane person we employ methods similar to those in sizing up the mentality of our saner fellow-men; as in the multitudinous relations of life, our estimate of others is determined by their actions, from observed actions assuming the existence of certain guiding principles or impelling forces (instincts, desires, emotions, ideas); so we may reason that, given certain tendencies, beliefs or convictions, we may expect of an individual under given circumstances a certain course of conduct.

Binet likens the mind to a vast polypus of images, as he does the body to a polypus of cells, and says that mental activity results from the activity of images as the life of an organism results from the life of its cells.⁵ This vast collection of images,—varying with the organization, environment, and degree of culture of the individual,—received by the several avenues of sensation, registered by the memory, compared, classified, and continually reinforced and modified by later sensations, may be influenced by the imagination, transformed into emotion, and finally into muscular action,—how, we are yet unable to say, though we begin to understand the mechanism of such transformation. In abnormal mental states these processes are brought vividly to light, and it is here that psychological and medical science must meet if resulting phenomena are to be correctly interpreted. It is not my intention to stray far into the field of psychology, but reference to a few principles is necessary if I am to attempt even meagre

explanation of a few phenomena of the morbid mind. Ribot teaches that in health, all higher development of intellect is along the lines indicated by the complex of emotional conditions in the individual;⁶ ideas lingering in consciousness and attracting other ideas in harmony with them and with the general emotional tone. He has shown that the feelings are the most tenacious of all forms of mental activity;⁷ without them man would have few motives for action, nor would he desire to act. In many forms of mental disease we find that certain emotional states are not only the invariable accompaniment, but also the chief characteristic of the mental state and, even more manifestly than in health, they here represent the real forces which govern conduct. With progress of the malady we see the gradual but progressive waning of conflicting and opposing ideas, which less and less vigorously exert their inhibitory influence, until the emotional element predominates, all processes originated by the one morbidity active group tending to work out their definite results with a precision and certainty unknown in normal life. In estimating the tendency to dangerous acts, we therefore direct attention to the emotional element, outward manifestations of emotional processes becoming the important indices to these inner hidden forces, and their systematic study must go hand in hand with that of the defective, perverted or diseased physical states with which they are so intimately associated.

Regarding the different images as preserved and reproduced sensations, we discern important relations with physiological phenomena of the senses and their underlying cerebral basis. We may therefore reason concerning the mental phenomena of images precisely as we would about their physical basis;⁸ and in this we do not go beyond the limits of demonstrable knowledge, since the experiments of Féré and Binet prove the image to be a phenomenon resulting from an excitation of the sensory centers of the cortex.⁹ Further observation along psychological, clinical and pathological lines tends to confirm the findings of these investigators, and the argument that there is between perception and image identity of nature, identity of seat and only difference of degree; that every image contains a tendency towards action because of the motor elements included in the image (Ribot), gives us a sound working hypothesis which we can, and do apply practically in estimating the tendencies of the morbid mind with its invariable tendency to translate images into acts.

Since every psychic action presupposes previous nervous action,¹⁰ we cannot separate disorder of the brain from antecedent defect, disturbance, or perversion of nerve functions, and we aim, in estimating the significance of morbid mental phenomena, to interpret them in the light of the patient's past, seeking for evidence of previous abnormalities. Tracing back the patient's history for years may be necessary, but in this we find much that aids us, and though it is difficult to separate the morbid from the normal in individual cases, or to say definitely what is symptomatic of mental abnormality and what consistent with mental health, we begin to understand the significance of morbid tendencies, impulses, emotions, obsessions, etc., experience daily

confirming the observation that the variable manifestations of impaired or perverted nerve function which we class under the general term of neurasthenia, are common antecedents of mental disease;¹¹ and when cerebral symptoms of neurasthenia predominate in any case hampered with slight but manifest developmental defect, burdened with psychopathic heredity, or who carries with him some toxic substance of the extrinsic, bacterial or autochthonous class productive, as shown by Van Gersen, of degenerative change in the tissues of the brain in precisely the same manner as other organs,¹² it behooves us to early recognize more serious mental defect into which it develops and to inaugurate necessary precautionary measures against dangerous acts.

Ordinary life reveals many predictions of the most serious forms of insanity, as well as variations which show the transitions from the normal to the morbid state;¹³ this because every individual has his own habit of intellection, imagination and feeling depending on the nature of his organism.¹⁴ It has often been said that in mental aberration the patient presents ideas, beliefs and sentiments widely differing (or, indeed, quite opposite) from those entertained when in full possession of his faculties: This is misleading, since, in practice, careful analysis shows the psychical abnormality to have developed along the lines of nervous action peculiar to the individual when he was considered well in mind. Thus, the depressive forms of insanity are apt to occur in reserved, timid, scrupulous individuals,¹⁵ while those forms in which we meet with exaltation of the mental functions, attack by preference subjects of expansive and excitable temperament, young persons.¹⁶ Even more clearly is this shown in partial, or progressive systematized insanity, which affects, by preference, those of gloomy, suspicious, irritable character, and inclined to pride and misanthropy. Or, again, in the various forms of insanity associated with certain periods of life, we find the psychical symptoms taking their coloring from mental states normal to such periods, i. e., they are modifications, distortions, or perversions of such traits. In the insanities of puberty and adolescence, for instance, there is emotional disorder, loss of self-control, and impulsive violence. If of the depressive form tending to solitude, moroseness, excessive timidity, vague longings, tears and sadness. If of the exalted form, there are varying degrees of excitement manifested in excessive activity, turbulence, insomnia, continual tricks and annoyances, dissimulations and falsehoods. In the insanities of old age, we find psychical symptoms in keeping with the querulousness, suspicions and melancholy of senility.

The morbid mental state, whether of long or short duration, is marked by emotions either pleasant and agreeable or unpleasant and painful. Ribot has shown that as symptoms reveal to us the existence of a disease and not its essential nature, which must be sought in the hidden lesion of tissues and organs, so pleasure and pain are only effects which guide us in the search for causes hidden in the domain of the emotions;¹⁷ they depend upon the manner in which the nerve centers of the individual react to stimulation from without and on the inten-

sity of that reaction. Of the pleasant and agreeable mental states we encounter all degrees from the slight expansiveness, with the usual accompaniment of ideas of excess of physical vigor and mental accomplishment (singing, dancing and incessant muscular activity), to those of delirious grandeur, as fabulous wealth, great power, Divine inspiration, etc. These states are characterized by corresponding disorder of the emotions, instincts and acts; but through incoherence, mobility and incessant change, such patients are usually incapable of planning evil, and danger is menaced only through their impulsive acts.

Unpleasant and painful mental states are marked by depression, sadness and discouragement, with morbid ideas of poverty, ruin, weakness, disease, persecution, etc. There is concentration of the mind upon sad or painful ideas, this limitation and fixedness contrasting strongly with the mobility and diffuseness observed in pleasurable states. We may regard them as due to fatigue of exhaustion of the nervous centers, since a variable degree of motor inactivity is constantly their accompaniment. They are present in many forms of mental disease, and may lead to danger through suicide, self-mutilation, and, through convictions bringing as a result modes of living or of action, directly affecting the health of the patient.

Since painful mental states are the earliest manifestations of many forms of insanity, as well as the invariable and characteristic accompaniment of melancholia, it follows that they are frequently seen by the general practitioner; indeed, many cases run their entire course outside a hospital under the family physician's care. Often no thought of mental disease is seriously entertained until after attempt at suicide has been made. There are few cases of melancholia which do not, at some time during their course, entertain notions of suicide, and though no attempt may be made to carry them into execution because of the characters of indecision and inertia or motor inactivity peculiar to the mental state, it must not be forgotten that under sudden impulse, or unforeseen access of energy, these patients make way with themselves suddenly and without hesitation.

In the widely varying forms of melancholia, we note a fairly constant order of psychical symptoms; the basis is depression or dejection, and, though there may be some foundation of fact in death of relative, serious illness, loss of property, etc., it has been as its distinguishing features that "*it is excessive and out of proportion to its apparent cause.*" Whether originating in this manner or entirely causeless and motiveless, it is early accompanied by mild thought inhibition or inhibited association; there is inability to fix the attention upon anything not in keeping with the emotional state, and soon, everyday occurrences and ordinary experiences come to be interpreted in the light of existing morbid emotions. This state may long precede sense deceptions and delusions, which are accidental and non-essential attendant symptoms (Ziehen) being developed secondarily from the dejection. The dejection, always primary, remains constant throughout the course of the disease, though its intensity may vary within very wide limits. Next appear

anxious states which also may be continuous, but are usually paroxysmally intensified; they may be regarded as exacerbations (attacks of anxiety), which occur at different times and vary in duration from minutes to hours. At such times the inhibited association may be prominently manifested in retarded flow of thought as well as in retarded voluntary movement, but the ideas and movements induced by the anxiety, are unaffected by the generally inhibited association,¹⁹ and, at these times, the morbid train of thought may rapidly translate itself into appropriate, accompanying acts upon so slight a determining circumstance as the sight of a weapon or the presentation of opportunity. The danger of suicide in melancholia becomes one, the gravity of which cannot be overestimated. Peculiarities in the manner of attitude of the patient may be the only signs pointing to the existence of morbid tendencies; but, while the patient's mental state is unmistakably shown by actions, in themselves, these afford no indication of the degree of danger. From that classification of melancholia, based upon the diverse character of the motor reaction to the emotional disturbance, we note that the form which presents the slightest outward manifestation of the mental state is one in which exists the greatest danger of suicide: Thus, while attempts occur in melancholia passiva, melancholia agitata and melancholia attonita, danger is greatest in the last-named because the apparently calm manner of the patient is apt to find one off guard, and the deed may be accomplished before disposition to suicide is suspected. Tendency to sit and brood, apparent apathy, attitude of dejection, evidences of apprehension of imaginary danger manifested by "fear in all its varieties, from simple scruple to panic terror" these become important criteria of the depressive mental states which threaten danger and should prove sufficient warning.

As threatening danger to property and to others, we must include all subjects of "falsified impressions of the outer world" in the way of suspicions and ideas of persecution, which may or may not be accompanied by the cardinal symptoms of insanity; hallucinations and delusions may precede or accompany the earlier emotional manifestations, but usually they follow them. These peculiar emotional manifestations are found in many forms of insanity, but are oftenest seen by the physician as accompaniments of epilepsy, imbecility, and the chronic intoxication psychoses. The invariable tendency in epileptics to painful feelings, manifested in moroseness, susceptibility to groundless dislikes, impulsiveness and irascibility, is so prominent that the note of their character has been summed up in the word "irritability": It follows, therefore, that epileptic insanity is marked by tendency to acts of violence. Berkley writes: "A large proportion of cases of sudden maniacal excitement of a violent, impulsive character, but of transient duration, lasting only a few hours or a day, are nothing more than instances of masked epilepsy, followed by blind, furious excitement".²⁰ Impulsiveness, equally with the irritability, becomes a characteristic feature of epilepsy, and, in the various forms of alienation which accompany it, leads us to expect the sudden acts of violence which are invariably the

outcome of this form of insanity. Here, again, we note their harmony with the emotional states which characterize the psychosis; we continually see unfounded aversions toward relatives, friends, or attendants, developing into conscious anger, thence passing into uncontrollable fury with the commission of homicidal acts under varying conditions of complete or clouded consciousness.²¹ In agreement with other authorities, Berkley writes: "No form of insanity more frequently gives rise to assaults and murders than epilepsy, and in no form of alienation is the physician so frequently called to the witness-stand to determine the responsibility of the criminal."²² Characteristics distinguishing this from other forms of insanity are: unfounded suspicions and aversions, ideas of persecution with a tendency to fits of passion and especially to irresistible impulses (homicide, suicide), and finally its co-existence with terrifying hallucinations.

The manner and attitude of these patients indicate their chronic mental state of suspicion and distrust, even more clearly than their expressed aversions and suspicions. It is important to remember that these may not differ very widely from normal manifestations of emotion, nor is the starting point of a paroxysm of rage always an imaginary injury; anger, originating in some trivial circumstance, may develop in much the same way as a common manifestation of this emotion, but soon reaches a stage of blind and violent motor excitement, with overwhelming fury. Among epileptics we find all gradations from the patient manifesting but slight surliness and irascibility to the one with frequent outbursts of fury accompanied by brutal and violent actions. It is important to remember that the victim of this psychosis may at any time suffer such violent attack, though previous manifestation of his malady has been atypical and obscure. With unmistakable points in family and personal history, and proof that dangerous tendencies have once been shown, we can, with confidence, predict a further development of his malady, when attacks of rage and fury, and proclivity to impulsive acts of violence will necessitate commitment to some place especially designed for his care and safe keeping.

In estimating the tendency to commission of violent and dangerous acts, this class, with that of imbecility, presents problems of comparatively easy solution: the chief elements to be considered are the character and intensity of the emotional state, remembering that any sudden, intense emotion, whether originating in fact or fancy, is promptly translated into appropriate action.

A class of cases oftenest coming under the care of the psychiatrist after the commission of some act which brings them within the cognizance of the law, is that of imbecility in its various grades. In cases of manifest defect early coming under the notice of the family physician, important points to remember—after determination of its degree—are: that they are incapable of a consecutive course of conduct and of doing anything in earnest; are capable of showing only the less elevated sentiments and affections, and the lower instincts dominate them. They are liable to be seized more or less suddenly with maniacal or melancholic attacks, at which times they are particularly liable to commit acts of

violence, robbery, suicide, or homicide.²⁴ Experience teaches that even in ordinary cases of neurasthenia, anxiety or excitement, in fact, any emotional stress, is fraught with danger to the individual. We can, therefore, readily appreciate the disturbing influence of emotion upon the defective, in whom the higher controlling or inhibitory forces do not operate because they have never been developed. In the imbecile, as in other forms, it is a matter of indifference whether the disturbing emotions have some basis in irritating circumstance, or whether they are imaginary as regards their causes; we have only to note their effects which are too often calamitous as regards society.

The following variety of insanity, not infrequently seen, in its simpler forms, runs a course so uniform and distinct that it should present few difficulties in diagnosis. Not rarely, however, fully developed and typical cases are objects of hard fought controversies in the criminal and civil courts, while the milder and less apparent ones render life almost unbearable to those who are subjected to their eccentricities and revengeful disposition; in immature, incomplete and mixed forms, however, they may confuse even the expert psychiatrist. The beginning of partial, persecutory, progressive, systematized insanity or paranoia, as it is variously called, is very often supposed to date from the time of commission of some act, which should be regarded as simply the final expression of a previous stage of longer or shorter duration. At the present time, I have under my care a typical case, who, for thirty-five years, wandered from state to state, driven hither and thither as a result of his delusions, yet certified as insane only six months ago.

Early recognition of persecutory insanity is of the greatest importance because the affected individual is highly dangerous to society. Regis writes: "Equally with the epileptics and possibly even more than these, the persecutory insane are, of all lunatics the most dangerous. The greater part of crimes committed outside of the asylums by the insane, and nearly all those committed within them, are to be credited to this class. Moreover, it is not only homicides that they commit; they may attempt arson, poisoning, and occasionally, contrary to general opinion and in exceptional cases, suicide." During the last four years, of three successful suicidal attempts occurring at the Western Pennsylvania Hospital for the Insane, two were of this class.

The evolution of partial, reasoning or persecutory insanity is so gradual that the significance of early symptoms is rarely appreciated. Since it attacks by preference those of gloomy, suspicious, irritable character, the earliest observed manifestations, in one of this type, very frequently have apparent foundation of fact in some slighting circumstance, neglect or aversion of relatives and friends, and consequently they are not given the importance deserved as symptoms of mental aberration. That there should be exhibition of aversion on the part of those who have suffered most from the patient's whims, eccentricities, and suspicious and revengeful disposition, is not surprising when we consider that incipient insanity is usually the last explanation to be given them; but they play no insignificant part in confirming and fixing his delusions. We thus

early have manifested the essential mark of this form of insanity, which, in its complete development, is the "idea of persecution," and we find all grades from apparently well founded suspicion of conspiracy coupled with resentment to the most elaborately systematized, though preposterous ideas of influence by hypnotism, poisons, electricity, X-rays, etc. Its origin depends upon peculiarities of organization: modifications of this, whether due to disappointment or emotional stress of any kind, exhaustion, bodily disease or indulgence in intoxicants and narcotics, bring about endeavor on the part of the sufferer to explain disordered sensations which thus originate in some imperfect adaptation of his organism. The evolution of the idea of persecution can often be traced to some disordered sense-impression, attributed by the patient to his environment; morbid sense of injury develops into a belief that he is defrauded, conspired against, acted upon by unseen agencies. A vindictive feeling next becomes manifest and danger now threatens. Regis writes: "The greatest peril any one can incur is to be taken by a persecutory lunatic for the head of the conspiracy that surrounds him, for the person against whom he must avenge himself; a peril that is the greater, since the victim is ignorant of it, and the patient in full possession of his mental resources, puts in the service of his enmity an astuteness and a cruelty truly Machiavellian."²⁵

Early manifestations of this form of insanity are few; indeed, they may not be apparent to those most intimately associated with the patient. Though influenced by the most violent imaginings and emotions in keeping with his morbid or insane ideas, it is the rule that he keeps to himself and gives slight outward demonstration of suspicions, hallucinations or delusions. The character of his morbid ideas may be inferred, however, from the objective marks of the accompanying emotional state; these are:—cold, harsh and suspicious manner; short and surly speech, often limited to a few characteristic phrases, such as: "I have nothing to say to you." "You know it better than I," etc.²⁶ As the disease develops, he may often be seen in silent converse, or even replying to himself, frowning or smiling at his own remarks, answering them, or giving way under their influence to sudden acts of eccentricity or violence.²⁷ Reticence, secretiveness, cunning, are such prominent traits as to form characteristics of their condition; and, for some time after commitment to an asylum or incarceration in prison as a result of the commission of some overt act (when they usually exert all the self-control of which they are capable), these may be their only diagnostic features.

Bearing in mind the character of the emotions accompanying this form of insanity, which, even as exhibited by normal man, are those most apt to overcome all higher restraining considerations and to terminate in overt acts, we can better appreciate their significance when manifested by the morbid mind, with the higher functions of the will weakened or abrogated, and how they must eventuate in action,—either in the blind, brutal sort, born of the instinct of self-preservation and determined in its manifestation by the most fortuitous circumstance, or that which is the gradual outcome of resentment,

rancor and hatred—the “deferred aggression” resulting in milder persecutions of the suspected one, or possibly suits at law. The various phases of this form of insanity, e. g., religious, political, erotic,—are evolved in much the same manner as the persecutory form and present dangers indicated by the prevailing emotional state.

Because the frequency with which they are encountered, as well as their instructive phases, those forms of insanity produced by the use of intoxicants, and narcotics, deserve more detailed consideration than can be given them in this paper. In none are the varying disorders in mechanism of intellect, emotions and instincts more clearly seen or more readily followed to their final exploiting in action. From the case of acute intoxication, produced and disappearing within twenty-four hours, to that of chronic alcoholism with accompanying characteristic brain changes, we constantly note morbid psychical manifestations, the variety and extent of which are measured only by individual variation and the complexity of man's nervous organization. To the early and profound involvement of the perceptive and emotional faculties is due, not only the pronounced tendency to exaggerate everything, but also the instantaneous acceptance of the false testimony of the disordered senses. The wrongly interpreted sense-impressions give rise to the illusions so common in delirium tremens: later, the more forcible continuation of the feeble image of internal origin giving rise to the vivid image which appears as an external object; further developing into the ideal and emotional phenomena where we see unfounded doubts and suspicions becoming certainties to the patient: All these evidenced early by accompanying emotional states so characteristic as to be unmistakable, in whatever form they may be manifest. In the maniacal form, we note the familiar phenomena of delirium tremens. In the melancholy form, all the dangers common to depressed mental states confront us, and these in exaggerated form; a tendency to suicide is the rule and often shows itself by a sudden unpremeditated attempt.²⁸ Impulses to destructive violence and ruthlessness characterize it, as they do epileptic insanity, originating in the unreasonable irritability common to both forms. In development of the chronic intoxication psychoses, symptoms common to both epileptic and persecutory insanity are observed, these varying phenomena being explained by familiar psychopathological laws.

In states of dementia, including paralytic and senile, the main tendency is towards weakness, and dangers which may arise are usually the outcome of failure in memory, mental confusion, extravagant conduct, and marked departure from the normal in appreciation of the fitness of things in domestic relations and in sense of propriety; they may occasionally exhibit suicidal, homicidal or self-mutilatory tendencies, but these develop as the result of underlying melancholy, hypochondriacal or suspicious states and are manifested as in other forms of

insanity. The knowledge that such tendencies frequently accompany the devolutional insanities is sufficient warning to bring the proper precautionary measures.

In all forms of insanity the morbid mental phenomena, which vary so greatly in character and intensity,—in so many cases obscure and apparently without order or system,—are, nevertheless, manifested according to well-defined psychopathological laws; interpreted by their light, resultant actions become comprehensible to us, and, in so far as they conform in their principal features to definite, known types of mental disease, their meaning is made entirely intelligible.

In this fragmentary and incomplete manner I have attempted to indicate the mechanism of the processes of feeling and acting which precede, as well as accompany, the cardinal symptoms of insanity and to point out the irrational procedure of suspending judgment until after the appearance of said cardinal symptoms in the potentially dangerous psychopath. My object has been to indicate those mental states which oftenest threaten danger, and to emphasize the import of emotions and their objective marks considered as symptoms, with their tendency to be translated into acts. I have omitted reference to accompanying physical states; these, it must be remembered, are inseparable from the psychical symptoms, the foundation of which they form: I shall not further dwell upon them except to say that in practice, the psychiatrist deals with mind in its morbid manifestations plus defective or diseased physical conditions. It is a statement of Weir Mitchell's that “the thinking general practitioner knows that what he has to deal with is not disease, but a disease plus a man.” This is deeply true of insanity. Nowhere is it more needful to study the human soil in which the disease exists.”²⁹ This involves questions of heredity, developmental defect, predisposition or vulnerability, incidental or exciting causes as toxic substances—either chemical poisons (alcohol, lead, etc.), microbic poisons (syphilis), together with the innumerable influences of environment.

From the view-point of the physician, the essential features of any case of mental aberration have their origin in the underlying morbid conditions which cause the disease, and early appreciation of these, with the significance of early psychical symptoms, brings practical results. *First:* In the prevention of mental disease in one predisposed by proper regulation of his life and placing the individual beyond the reach of diverting and disturbing circumstances. *Second:* In early placing him under the most favorable conditions allowing his weakened cerebral centers to recuperate. *Third:* The better performance of our duty to society in more effectually preventing danger to patient, property and to others.

Not always does the psychiatrist or neurologist have these opportunities of prevention. The incalculable advantages of knowledge of family his-

tory and inherited conditions, diseases of early life and modifications of the organism thereby, variations in metabolic and nutritional functions, together with the influences of education and environment, are all given to the family physician, and, it is no exaggeration to say, place him in position to prevent, or to combat and control morbid mental conditions before they are fully developed.

DEUTSCHE ZEITSCHRIFT FUER CHIRURGIE.

April, 1901. (Volume 59, Nos. 3 and 4).

11. A Sebaceous Adenoma in the Umbilicus. WILHELM von NOORDEN.
12. Antiperistalsis. ENDERLEN and HESS.
13. Some Operations upon the Large Intestine. ERWIN PAYR.
14. Strumitis after Pneumonia. SCHLENDER.
15. Tuberculous Peritonitis. J. LAUPER.
16. The Statistics and Treatment of Carcinoma of the Rectum. KARL VOGEL.

11.—Von Noorden reports a **unique case of sebaceous adenoma of the umbilicus**. A woman, aged 38, with excellent family and previous history, noticed an unevenness in her navel two months before operation. Upon examination a tumor was found in the umbilicus about the size of a pea. This increased in size and was removed by operation two weeks later. A stitch abscess resulted, but recovery followed, and three years afterward she was quite well. Histological and microscopical examination showed distinct sebaceous glands in the abdominal wall removed with the tumor; the tumor had a covering like that about the sweat glands; the epithelium was that of the sebaceous glands; and its character was tubulous above, and cystic below. It was diagnosed a **fibro-cystic sebaceous adenoma**. The tubulous character of its upper layers and the retention cysts below were especially noticeable. There seems no doubt that the tumor developed from the sweat glands, but from causes unknown. A full review of the literature of benign and malignant tumors of the sebaceous glands and of the navel is given. Von Noorden suggests that the yolk-sac of the embryo may have left some tissue in the navel which might later form an adenoma or carcinoma of the umbilicus. Such tumors are very rare. But this case shows that a benign adenoma arising from the sebaceous glands can exist in the umbilicus. [M. O.]

12.—After a review of the experiments performed to determine the normal intestinal movements, both peristalsis and rhythmic contractions, with a full resumé of the literature of the subject, Enderlen and Hess describe their own experiments upon dogs. The intestines were reversed, yet digestion occurred quite normally, and the animals kept in good health. Thus antiperistalsis undoubtedly occurs. Antiperistalsis is also seen with vomiting when intestinal obstruction occurs in man. [M. O.]

13.—Payr reviews the **technique of several operations upon the colon**, quoting the work of many operators. His own ideas are illustrated with diagrams. In resection and amputation of the rectum, the proximal end of the intestine will be kept in good condition by employing a **large, specially made Murphy button**. Great care must be taken to operate rapidly; not to permit the end of the intestine to be drawn back into the abdominal cavity; and to prevent infection, either peritoneal or external. This special button

is serviceable for colectomy or colostomy. It can also be used in the formation of an intestinal fistula by any method. On account of the rapidity of the operation when this large button is employed, it is especially of use when colostomy is necessary for intestinal occlusion. Many technical details are given.

14.—Schlender reports a case of strumitis which occurred in a man of 52, who had first noted symptoms twelve years before. Some years later vertigo and headache appeared. This year croupous pneumonia appeared suddenly. Four days later the thyroid began to swell perceptibly. Dyspnea appeared, and became almost asphyxia. The pain in the neck also grew worse. Exploratory puncture of the thyroid revealed pus. This was then incised and irrigated. A diastolic murmur was audible all over the heart, the pneumonia cleared up, and he died. The autopsy showed abscess of the thyroid gland, malignant verrucous endocarditis of the aortic valve, a tumor and anemic infarct in the left kidney, and hyperplasia of the splenic pulp. The temperature did not fall after operation. Such cases of general infection following strumitis are rare. Both **diplococci and streptococci** were found in the pus. After reviewing the literature Schlender concludes that the prognosis in strumitis is uncertain before operative interference; that it depends upon the sort of bacteria found in the pus; and that those cases of metastatic strumitis which appear late will run a more favorable course than those which appear early. [M. O.]

15.—Lauper reports 22 cases of tuberculous peritonitis, 14 of which were operated, the other 8 being tapped and treated medically. The histories of these patients are fully given, illustrated with diagrams. Tuberculous peritonitis is more frequent in women due to the susceptibility of their internal genitalia to the tubercle bacillus. Sixteen of his cases were women. The great majority became ill between the ages of 25 and 30. Heredity plays an important predisposing role. Over 80% of the cases showed marked pain at the beginning of the disease. From his cases, Lauper believes that the occurrence of fever is of no prognostic significance. Nor is fever ever a contraindication to operation. To a certain extent, tuberculous peritonitis recovers spontaneously. Those cases give an especially favorable prognosis in which the source of the infection, as a pyosalpinx, has been removed by operating. Laparotomy is indicated in the serous, exudative, and adhesive forms of tuberculous peritonitis. Operation will be followed by the best results when attention is paid, besides, to better hygiene, rest in bed, strict diet, and the treatment of the other complicating tubercular affections. Of Lauper's operated cases only three showed no improvement at all, and two of these had outspoken pulmonary tuberculosis. [M. O.]

16.—Vogel reports 61 cases of **cancer of the rectum**, 48 of which were operated upon by Schede. The rest were treated palliatively. Thirty-five were in men, of whom 25 were operable. The average age of the men operated upon was 60, of the women, 50. The women who were treated palliatively were younger. The main complaint on admission was the passage of blood and mucus from the bowel, with or without defecation. There were also pain, tenesmus, constipation, etc., for some months. The only contraindications to operation are great weakness, and metastases or growths into important organs. Vogel prefers operation by the perineal method, with resection of the coccyx, which was done in 26 cases. Five of these were again operated. Out of these 31 operations, only 7 patients died. The tumor recurred in 10 cases, after an average of 10 months. The other 22 operations were through the sacrum, after Rydygler's temporary osteoplastic resection of the sacrum. In these cases, hemorrhage, stercoral fistula, disturbance of the bladder, etc., followed. There were no deaths from peritonitis. Of the 22 cases, 10 died, mostly from collapse. There was recurrence in three others. The histories of the 61 cases are given in full, with detailed descriptions of the operations. Statistics of other operators are compared with Schede's results, which were 17 deaths from 66 cases; recurrence in 13 out of 32 patients; and 6 cases of the 48 cases operated upon are alive and well over three years after operation. Of the 13 inoperable cases, colostomy was done in 10 patients. Vogel has filled the article with interesting comparative statistics. A long bibliography follows. [M. O.]

VOL. VIII, NO. 2

JULY 13, 1901

\$3.00 PER ANNUM

The Hot Weather.—Such weather as the country has suffered from recently is almost as bad as a pestilence. On Tuesday, July 2nd, the official record for Philadelphia was 103 degrees, a range of temperature which has been equalled but rarely in this city in the experience of living men. This phenomenal day, however, was merely the crisis of a prolonged overheated period, which was almost if not quite unprecedented. The cost of such weather in life and treasure is hard to estimate. The death rate in Philadelphia was increased very greatly, but is not easy to determine the exact number of deaths due to the heat. In the midst of a "hot wave" almost every sudden or speedy death is attributed to the weather. Many deaths are doubtless due to other direct or contributory causes, such as apoplexy, alcoholism and heart and kidney diseases; still the mortality in large cities from such heat is evidently very great. The Bureau of Health from Monday until Friday is reported to have issued death certificates for 208 persons who are said to have died from the effects of the heat. At one time in the week there were 49 dead bodies in the Morgue. The highest death rate ever recorded in this city during a heated term was reached during this period. This death rate, in fact, is little less than appalling. The total number of burial permits issued for all cases for the week was 1088—the greatest number issued in one week since the establishment of the Bureau. Five hundred horses died from heat in this city in the two hottest days, according to one veterinarian.

The hospitals have been severely taxed, but have met the emergency nobly. The public should understand that this means a great additional expense to these institutions. By way of scientific treatment, something new is claimed for saline infusion. This method is said by some to give better results in thermic fever than the cold bathing. It is too early for us to reach any judgment, but we trust some accurate reports will be forthcoming with reference not only to this, but every other form of treatment.

More About Anesthetics.—The problem of anesthesia will not stay down. Ever and again it rises in

one form or another to prove to the world that, despite all study and apparatus, it has not yet been thoroughly solved. There can be no question that ether is not an ideal anesthetic, although in this country it is, and to an interesting extent in England and on the continent of Europe it is becoming, the favorite of surgeons. The objections are obvious. The irritation of the throat, with consequent excessive secretion of mucus and saliva, resulting in difficult respiration and occasionally in cyanosis; the slowness with which the anesthesia is produced; the difficulty in producing it in alcoholics; and the fatal subsequent effects of the form of inspiration pneumonia and renal irritation, and possibly weakness of the heart, must always be taken into account. On the other hand, chloroform, which has so few of these disadvantages, has the fatal defect of causing not infrequently paralysis of the heart or respiration during administration. Recently, Braun (*Muenchener Medicinische Wochenschrift*, May 14, '01) has suggested a modification which to his mind solves the problem; as many men have thought to solve it before, by the introduction of some modification. But Braun's method deserves much credit for its ingenuity, and the results which he reports are quite imposing. He believes that a mixture of the vapor of chloroform and ether, well diluted with air, will anesthetize the patient very rapidly, irritate the fauces but slightly, and avoids most of the immediate dangers of either method alone. Simple mixtures of ether and chloroform cannot be used with advantage on account of the fact that in the early stages the proportion of the ether vapor is greatly in excess of the chloroform vapor, and in the latter stages the chloroform vapor becomes predominant; exactly the reverse of the condition that would normally be desired. He has, therefore, contrived an apparatus which he believes furnishes a constant supply of diluted vapor in uniform proportion. This consists essentially of two bottles of different sizes, each with a cork perforated with two holes. Through one of these holes a long tube is passed which is united with another tube passing through the cork of the other bottle by two rubber tubes and a "T". To the free end of the T another rubber tube is at-

tached at the end of which there is a rubber bulb and a balloon, so that air can be pumped into the bottles. The capacity of the bulb should be about 90 ccm., of the larger flask 200 ccm., and of the smaller flask 100 ccm. Through the other holes in the corks two other tubes are passed, stopping above the level of the liquid, and also connected by two rubber tubes and a "T". The other end of the tube communicates with a metal mouth-piece supplied with a valve on one side. The ends of the long tubes are supplied with stop cocks regulating the amount of air that is admitted into the mouth. The mouth-piece is placed over the patient's mouth and nose, the stop-cocks arranged, and air pumped in at the beginning of each inspiration. When both stop-cocks are open, about 4 parts of ether vapor to one of chloroform vapor well diluted with air, are administered. Usually it is desirable, as soon as the patient loses consciousness, but before the corneal reflex is lost, to close the stop-cock in the chloroform flask and to continue narcotization with the ether alone. If the patient begins to recover during the operation, a small quantity of chloroform should be again employed. In cases in which operations are performed upon the mouth, the metal funnel is replaced by a small tube passed through the nose into the pharynx, and the vapor is delivered directly to the larynx.

Braun has used his method in 250 cases. The average duration of narcosis was 47 minutes, the maximum, however, was $3\frac{1}{2}$ hours. The average amount of ether used was 54 ccm.; of chloroform, 12 ccm. Usually it required from 6 to 8 minutes to render a patient unconscious. Whether this method, which appears to have something to recommend it, will succeed in obtaining general employment or not, remains to be seen. The fear of chloroform in this country is so great that it probably will require more than 250 cases (even though these all terminated very satisfactorily) to secure its recognition.

The Influence of Diseases of the Aorta upon the Development of Pulmonary Tuberculosis.—Although all individuals are more or less exposed to infection by the bacillus tuberculosis, only a few develop tuberculous disease. Why it should be that of two persons exposed to the same infection one should contract the disease and the other escape, has been explained by the greater resistance of the tissues of the one who remains healthy. Beuchet, in his *Paris Thesis* (*Gaz. Heb. de Med. et de Chirur.*, May 12 1901), calls attention to the fact that diseases of the heart in general have a varying influence upon the course of pulmonary tuberculosis. This influence depends upon the circulatory

modifications which the heart lesion produces in the pulmonary apparatus. When the cardiac lesion produces blood stasis in the lung, the course of the disease is retarded and takes on a more benign character. When, on the other hand, cardiac disease produces ischemia of the lungs the pulmonary lesion is made more extensive and its course is more rapid. Aneurysm of the aorta may cause compression of the bronchi and of the lungs or compression of the pulmonary artery and the pulmonary nerves. These effects may exist singly or in combination. If there is a tuberculous process in the lungs in addition to the aneurysm, the pulmonary disease may be influenced in its course, and its evolution by the arterial lesion. Aortitis and arteriosclerosis favor the development of tuberculosis by slowing the blood stream on account of the loss of elasticity and of the narrowing of the caliber of the vessels, thus creating a deficient blood supply, defective nutrition and an anemia favorable to the multiplication of the tubercle bacilli. It is inexact to think that in such patients the pulmonary lesions should tend to sclerosis alone, for, although these lesions do not progress in some cases beyond the stage of induration and take on a fibrous form, they also frequently become soft and end in ulcerative lesions with loss of lung substance. This relation between pulmonary tuberculosis and diseases of the aorta is worthy of further study, and it would be interesting to know the percentage of patients who die from pulmonary tuberculosis who also present aortitis.

An Apology for the Bath.—Florence Nightingale once said that a person could wash and be clean with only a quart of water, but she spoke probably from necessity, not choice, for she had been a nurse in the Crimea, where water doubtless was scarce. When she was in England, we suspect, she took to her tub. Now comes Dr. C. W. Lyman, in *The New Voice*, and tries to make us believe that bathing is only a compromise of civilization. In a real state of nature, according to some German professor whom he quotes, man would require no bathing. His skin would be exposed constantly to the sun and wind and rain, and would be "brushed by dewy branches and grasses." This sort of thing, according to Dr. Lyman and the German professor, would be sufficient to keep a man clean. They take no account of the fact that many primitive people are great swimmers and bathers in the rivers, lakes and sea. Where they find the "state of nature" about which they talk so glibly, we do not know. They think that "we need constantly to work back toward the superb skin circulation of the savage"—in order to do which they imply that we should all

go naked and never bathe. The skin, they claim, when exposed to all the vicissitudes of the weather, develops a vastly more extensive circulation than is seen in the clothed men of civilization.

From all which it appears that only wild men do not need to bathe, and that the bath-tub is derided and avoided only by savages and theorists.

The Army Nurses.—If newspaper enterprise could be restricted to exploiting the simple truth, it would be not only more profitable but also more interesting. This thing of printing bogus interviews (especially on medical subjects) has become a crying evil. Thus a Philadelphia newspaper recently published what purported to be an interview with Mrs. D. H. Kinney, who is absurdly called the "Acting Assistant Surgeon General of the Army Nurse Corps," but who is in reality the superintendent of nurses. Mrs. Kinney has taken the newspaper roundly to task, and contradicts it especially as follows: The office was created by Congress, and not by another woman who once held it. There is not, and there never will be, a training school connected with a United States military hospital. The employing of trained nurses in United States military hospitals was never thought of before the Spanish-American war. There has never been any difficulty in securing competent nurses; the trouble has been to select from among the thousands who have applied. Of 7769 applicants, 1500 have been employed. The Surgeon General does not approve and has never allowed nurses on the battlefield or near the firing line. The highest percentage of sick in the hospitals under favorable conditions is not more than 9% to 10%. There are at present only about 200 members of the army nurse corps.

The sensational reporter had misstated or exaggerated all these simple details in order to make a more "readable" bit of copy. Now his newspaper is obliged to eat his words, but this does not remedy the evil that may come from misrepresenting an important arm of the medical service, neither does it enhance the reputation of newspaper reports on medical subjects.

Diphtheria in Epileptics.—Fradin (*Gaz. Heb. de Med. et de Chirur.*, May 26, 1901, *Paris Thesis*. No. 277) has studied the action of diphtheria upon epileptic crises during an epidemic of diphtheria in the Salpêtrière during the past year. He has found that during the height of the attack of diphtheria the epileptic crises are completely arrested and that during convalescence the seizures gradually return. An infectious process like diphtheria, while it modifies the epilepsy for a time, does not influence its general course. If an epileptic patient who is suffering from an infectious disease has a convulsion,

or if he has an attack of vertigo, the nervous phenomenon will usually be accompanied by a rise of temperature. The treatment of diphtheria in epileptics presents no particular indication. The therapeutic use of antidiphtheritic serum in degenerates gives rise to complications that are more marked the lower the individual is placed in the intellectual scale.

Narcolepsy.—Narcolepsy is clearly distinct from all other varieties of pathological sleep. Furet, in his *Paris Thesis* (*Gaz. Heb. de Med. et de Chirur.*, June 2, 1901), advances the opinion that narcolepsy is a symptom of autointoxication. The condition is observed in the course of diseases of nutrition, such as diabetes and obesity; during the acute micro-organismal diseases, such as influenza, typhoid and typhus fevers; as a complication of the intoxications, such as alcoholism, all of which may be considered as producing autointoxication. Often other symptoms of intoxication, such as epileptic seizures, are coincident with narcolepsy. The narcotizing action of toxic substances, such as opium and its derivatives, chloral, etc.; the fact that there are cases on record in which narcolepsy disappeared at the same time as did the disorders of nutrition; the toxic theory of Breyer and Léo Eréra, partly confirmed by the experiments of Bouchard on urinary toxicity, are arguments in favor of the author's view that narcolepsy is a symptom of autointoxication. The gravity of the condition depends upon the affection in the course of which it develops. The treatment consists in suppressing the cause of the intoxication, such as alcohol or excessive eating, and of favoring the elimination of the toxin by milk diet, purges and injections.

Uniform Medical Legislation.—The preliminary report of the Committee on Organization of the American Medical Association (see *Journal of the American Medical Association* of May 25th, 1901), while speaking of the reorganization, mentions prominently medical education and medical legislation and reciprocity. We sincerely hope, not only that these two most important questions will receive due consideration on the part of the House of Delegates, and of the General Meeting, at Saratoga, but also that material progress will be made by advocating and endorsing such steps as may be recognized as commendable. It appears to us that a high standard of preliminary education, and a thorough medical course in a well equipped and continually inspected medical college, should be insisted upon. The example set by the New England Medical Boards, which formed a working group, should be recommended. These and similar considerations suggest themselves to the American Medi-

cal Association. Although a sub-committee on uniform medical legislation was appointed by the Conference of the Committees on National Legislation of the American Medical Association and affiliated societies, the responsibility, we think, rests upon the House of Delegates, and upon the General Meeting. Circumstances place the reorganized Association face to face with great problems. We feel assured that the American Medical Association will be equal to the task.

Hereditary Transmission of Acquired Immunity.

—Probably one of the most important problems confronting the bacteriologist is that of immunity, a problem which so far seems to baffle all efforts at a satisfactory solution. We know what the manifestations of immunity are, but as to the whys and wherefores we are still in the domain of theories which at best are only plausible hypotheses. Immunity is usually divided into natural and acquired; the latter again into active and passive. So far as the immediate effect on the individual is concerned, both natural and acquired immunity are alike in protecting him against infection, but there is a sharp dividing line between the two, indicating that they are distinct biological phenomena. Natural immunity is racial and transmitted from the parent to the offspring, while the acquired is confined to the individual, and may be transmitted in the form of a passive immunity which is but of brief duration, from a few days to 2-3 months. Accepting Weismann's theory that acquired characteristics are not transmitted, we can well conceive how acquired immunity, being an acquired characteristic, dies with the individual. On the other hand, natural immunity owes its existence to the survival of the fittest, an evolutionary process by which the individuals susceptible to a given infection are gradually eliminated. The passive immunity conferred upon the offspring by the immunized parents has been observed by Wernike in the case of diphtheria, Ehrlich in the case of tetanus, and a number of other investigators. It has also been noted that the immunity is transmitted by the mother, but not the father. Experimental proof, as well as an explanation of this phenomenon, is found in a recent contribution to the *Archiv. Biologischesch. Nauk* (Vol. VIII, No. 3) by C. K. Dzerzhowski. This author found that the testicular fluid of a horse possessing a high degree of active immunity, is practically devoid of antitoxin. On the other hand, the fluid of the Graafian follicles of immunized mares is very rich in antitoxin, equalling in some instances the blood serum. Similarly, the secretions of the prostate and Cowper's glands are very poor in antitoxins, while those of the uterus are but slightly inferior to the antitoxic serum. The

fertilized ovum, therefore, is constantly surrounded by an antitoxic medium and is consequently subjected to a process of passive immunization. This, however, is possible only up to the time of the formation of the placenta, for as soon as the direct interchange between the mother and embryo ceases, owing to the intervention of the placenta, the antitoxin no longer penetrates the tissues of the developing ovum. Experiments performed by the author show that neither the placental blood nor the amniotic fluid contains any antitoxin. Moreover, the remarkable fact was established that the placenta has a selective action, permitting neither toxins nor antitoxins to filter through. Any immunity, therefore, that the offspring of an immunized mother may possess is due entirely to the passive immunization acquired during the preplacental period.

Huxley and Owen.—In 1858 Huxley delivered the Croonian Lectures on "The Theory of the Vertebrate Skull," in which he proceeded to combat the opinion that the skull is formed of segments which are homologous to the vertebrae of the spinal column. This theory, if we remember correctly, was first suggested by the German poet Goethe. Huxley demonstrated from the embryological studies of Rathke and others, that after the first step, the whole course of development of the segments of the skull proceeded on different lines from that of the vertebral column, and that the imaginative theory of the skull as modified vertebrae was not in accord with the facts as he had observed them. Sir Michael Foster, in his obituary notice of Huxley, spoke of this "fantastic doctrine" as having been advocated by Owen, and said that Huxley, in criticising this doctrine, while acknowledging that the spinal column and the skull start from the same primitive condition, yet pointed out that they immediately begin to diverge, and that it is "no more true that the adult skull is a modified vertebral column than it would be to affirm that the vertebral column is a modified skull."

This controversy has special interest because, as pointed out by Huxley's recent biographer, it was a bold step for so young a man to challenge Owen, who was the acknowledged "autocrat" of science in Britain. Owen held to the theory of an "archetype" in anatomy, but such an idea was evidently repugnant to Huxley's whole philosophy. Moreover, Huxley had early conceived a dislike for Owen, as is clearly shown in his biography, and came to consider himself more than the latter's equal in morphology. He was not the man, either, who would tolerate an "autocrat" in science. For him science was a pure democracy—a conception

which it were wise for all of us to foster. The two scientists, Huxley and Owen, eventually broke off all personal intercourse, and their estrangement grew out of circumstances in which Owen seems to have been the aggressor. But Huxley's opinion of this "fantastic doctrine," which is still held by some morphologists, should be of interest to all medical readers.

The Index for Volume VII.—Owing to some alterations in the press room, the publication of the index for the last volume of the *Journal* has been temporarily delayed.

Reviews.

The Feeding of Infants. Home Guide for Modifying Milk.

By Joseph E. Winters, M. D., Professor of Diseases of Children, Cornell University Medical College, New York. E. P. Dutton & Company, 1901. Price 50 cents.

The book before us for comment is designed for the use of mothers and guardians who are obliged to feed their babies artificially. The author divides the milk as obtained in bottles into top milk and bottom milk and gives formulae for preparing percentage mixtures by the combination of these two varieties of milk with cream and water. The author is an advocate of the use of lime water in the mixture to render the acid cow's milk alkaline. He does not believe in Pasteurization. He states that tested by the standard of human milk there is not one of the so-called Infant Foods that fulfils one of the conditions required of a substitute for human milk. It has been repeatedly demonstrated that every infant food on the market is deficient in fat, milk, sugar and albuminoids. We recommend this attitude concerning Infant Foods and we believe that the use of lime water in making mixtures is of decided advantage. There are arguments in favor of Pasteurization as well as facts against the use of that process. If one is sure of his milk supply Pasteurization may be dispensed with; but in the promiscuous milk supply of a great city this process is probably the lesser of two evils. On the whole, the book is a safe and conservative home guide for Infant Feeding. There are blank pages at the end of the book for recording the baby's weight, etc. [J. M. S.]

Nursing Ethics for Hospital and Private Use. By Isabel Hampton Robb, J. B. Savage, Cleveland, 1901.

This little book, however much we may cavil at the title which has been selected for it, is a work painstakingly done, and written by a competent nurse who has ideals, and wishes to impart these ideals to others, who essay to fill the same professional career. There is a great deal of excellent advice given to those who are contemplating taking up the study of nursing, and especially valuable is that portion of the book dealing with the relations of graduate nurses to physicians, to other nurses and to the public. [T. L. C.]

Correspondence.

DANGERS TO THE LAITY.

Doctors Repudiate Professor Atwater's Theory of Food Value of Alcohol.

By T. D. CROTHERS, M. D., of Hartford, Conn.

To the Editor of the *Philadelphia Medical Journal*.

The American Medical Association has just held its annual meeting in St. Paul, Minn. During its sessions, the American Medical Temperance Association, composed of eminent physicians and teachers in medical colleges, members of the American Medical Association, always holds

one or more meetings for the special purpose of promoting scientific study and investigation into the action of alcohol in health and disease. The meeting this year shows a great advance in the scientific study of alcohol and its action on the body. In the ten years of its existence its membership has grown to over two hundred, and the number of papers and discussions, all of a scientific and technical character, is increasing, so that literally this is the most authoritative organization studying the alcohol question in this country. Of the ten papers read at the St. Paul meeting, three of them discussed Professor Atwater's experiments and conclusions, and the members then passed the following resolutions as the unanimous opinion of the Association:

"Whereas, the American Medical Temperance Association, the members of which are physicians and medical teachers who have devoted years to the study of alcohol and its effects, and who are conversant with the work done by scientific men the world over to determine the effects of alcohol when given in any quantity, have noted the teaching of Professor W. O. Atwater, of Wesleyan University, upon the food and medical value of alcohol as set forth by him in the pages of the influential lay press, be it

"Resolved, that this Association utterly repudiates the pro-alcoholic doctrine of the said Professor W. O. Atwater as being contrary to the evidence deduced by scientific experimentation, and that his conclusions are unwarranted by the evidence resulting from his own experiments. Be it further

"Resolved, That this Association regards the teaching of Professor W. O. Atwater as erroneous, and a source of danger to the laity inasmuch as such teaching contributes towards the increased consumption of alcoholic beverages by giving supposed reason for their safe use."

(Signed)

N. S. DAVIS, M. D., President, Chicago, Ill.

T. D. CROTHERS, M. D., Secretary,

Hartford, Conn.

Two other papers pointed out the evils from the use of cigarettes and tobacco on neurotics and young persons. One paper critically reviewed the school-book teachings of alcohol, sustaining their claim to scientific accuracy in nearly all the books used.

The address of both the President and Vice-President described the folly of efforts to check disease and degeneracy by ignoring alcohol as one of the active causes, also the conflict of experience with theory and tradition. The other papers read discussed the causes of the popularity of alcohol as a beverage, and its danger in high altitudes; also the substitutes for its use in medicine.

The value and reliability of these papers are evident from the fact that eight of the ten authors are active or emeritus professors in medical colleges. Four of them are medical journalists, two of whom are in active practice.

AN ERRONEOUS REPORT.

By GUSTAVUS M. BLECH, M. D., of Chicago.

To the Editor of the *Philadelphia Medical Journal*:

I deem it my duty to warn the medical profession not to depend on a reported decision handed by Judge Kavanagh, of Chicago, in a suit for damages against Dr. Franklin N. Martin and the Chicago Post-Graduate School. The notice has been published in the prominent medical weeklies of the United States and is not in accordance with facts—therefore misleading and apt to bring some surgeons into trouble.

The case in question is this: Prof. Martin undertook to operate on a woman for umbilical hernia. On opening the peritoneum he discovered a tubercular peritonitis and ovaritis. While this patient was still under the influence of the anesthetic, Dr. Martin, in order to save her life, extirpated her ovaries.

As so frequently happens in this country, where life and limb is estimated by juries in dollars and cents (including love-fractured hearts) ingratitude was shown and the patient entered suit for damages.

Judge Kavanagh maintained that the plaintiff made out no case in that she did not prove that the removal of the ovaries was not necessary. Council for the plaintiff contends that a negative fact cannot be proven and will appeal the case. Judge Kavanagh therefore never decided that a surgeon can perform additional operations without the consent of the patient and I would advise every

surgeon not to operate on any case without first receiving a written consent from the patient or relatives giving full authority to do whatever seems necessary to save life.

COCAINE ANESTHESIA.

By ELLAS SAWAHINI, M. D., of Boston, Mass.

To the Editor of the Philadelphia Medical Journal.

Dear Sir—With great interest I have been reading the articles on Cocaine Anesthesia that have appeared in your journal.

I have had a fairly good experience with cocaine and used it almost exclusively in Minor Surgery. I injected it locally in what I think is termed the "blocking" method in strengths varying from 10% to 2%. But in the greater majority of my cases I got swelling of the part, sometimes in quite a marked degree, so much so that the stitches would cut through from the second day, or I had to cut one or two to relieve the great tension and pain. I have used the Esmarch and operated without it but the results have been about the same.

I shall be very thankful if you or any of your readers would enlighten me as to the theory and how this thing might be prevented.

RATTLE-SNAKE VENOM.

By JOSEPH McFARLAND, M. D., of Philadelphia.

To the Editor of the Philadelphia Medical Journal:

In the course of some investigations which I recently conducted with rattle-snake venom there came into my possession a small quantity of dry venom which had been kept in an ordinary homeopathic phial, carelessly corked since the time of the researches of Mitchell and Reichert, which were made and published in 1886. The venom had therefore been dry for approximately 15 years.

I made a solution of it, and tested its strength upon rabbits and found it approximately as active as venoms which I had collected and dried a few weeks before. This is, I think the oldest dried venom that has been tested and the observation surely proves how very stable the venom is in the dry state.

GLENARD'S DISEASE.

By ACHILLES ROSE, M. D., of New York.

To the Editor of the Philadelphia Medical Journal:

In the issue for June 15th, of your esteemed journal, there is an editorial, "Gastroptosis," which contains some errors. To begin with the author of the editorial says, "Gastroptosis, or Glenard's Disease." This is the first time that I have seen Gastroptosis (which should properly be called Gastroptosis) identified with Glenard's Disease.

[We are fain to admit that the term "Glenard's Disease" is strictly not correctly used when applied to Gastroptosis. According to Glenard it is really a condition found in splanchnoptosis, but as gastroptosis is a mere characteristic feature of this disease, it is customary sometimes to use the part as standing for the whole. We agree, however, with our correspondent that splanchnoptosis would have been a better term.—Editor.]

Resection of the Wrist by Double Longitudinal Dorsopalmar Incision.—Dr. Francis Villar discusses the modes of resection of the wrist in the *Journal de Médecine de Bordeaux*, (1901, No. 17). The great objection to most of the methods advanced is the fact that they do not open the joint wide enough to see the extent of the lesion. But this objection will not stand against the transmetacarpal method of Studsgaard of Copenhagen, by double longitudinal dorso-palmar incision. It is easier than all other methods, and gives better results, both therapeutic and functional. It is indicated in osteo-arthritis of the carpal and metacarpal bones, and tuberculosis of the wrist, and it may save amputation. After describing the technique of the operation in detail, Villar concludes that it is easily executed; that it permits sufficient light to enter to follow both tendinous and osteo-articular lesions; that on this account it is indicated in widespread processes; and that the results obtained have been excellent. [M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Emergency Quarters.—During the excessive heat of last week the hospitals of Philadelphia were overcrowded, and many were obliged to erect tents for the purpose of quartering patients that had been overcome by the heat. Many business establishments fitted out portions of their buildings with all the necessities for the restoration of those suffering from heat prostration.

Enteric Fever in West Philadelphia.—It is stated that enteric fever is spreading, and that the Health Board has been quite active in endeavoring to trace the source of infection.

Free Hospital for Consumptives.—A movement is in progress for the establishment of a free hospital for consumptives in the mountains near Wilkesbarre, Pa. The donor of the land is said to be Dr. Trimmer, of White Haven, the land being situated on Green Mountain, overlooking White Haven and the Lehigh River. Dr. Lawrence F. Flick, President of the "Pennsylvania Society for the Prevention of Tuberculosis," and Dr. Thomas, who is a member of the "Committee on Plans," recently visited the proposed site, and believe that a bill appropriating one hundred thousand dollars for the project will meet with the approval of the Governor.

Pennsylvania State Medical Society.—The date of the annual meeting has been changed from September 17th to 19th to September 24th to 26th; the meeting is to be held in Philadelphia.

Pest House at Marcus Hook.—At the State Quarantine Station at Marcus Hook an emergency pest house has been erected, which will accommodate 500 patients. A new crematory has also been added to this plant.

Lehigh Valley Medical Association.—The Summer Meeting of the Lehigh Valley Medical Association will be held on Thursday, July 25th, at Mauch Chunk, Pa.

NEW JERSEY.

State Board of Medical Examiners of New Jersey.—At the annual meeting of the State Board of Medical Examiners, held at Newark, N. J., July 5, 1901, the following officers were elected: President, Dr. Charles A. Groves, East Orange; Treasurer, Dr. A. Uebelacker, Morristown; Secretary, Dr. E. L. B. Godfrey, Camden. Of the candidates examined, 29.4 per cent. were rejected.

NEW YORK.

Dr. Frank L. Christian, of New York City, has been appointed medical superintendent of the Elmira Reformatory.

Dr. Paul F. Munde, of New York, has resigned the chair of gynecology in Dartmouth College, which he had held for twenty years, and has been elected an emeritus professor of gynecology by the trustees.

Dr. Herbert M. Tolfree, of Buffalo, has been appointed to the medical corps of the navy and will be commissioned as an assistant surgeon.

New Hospital for Babies.—It is stated that plans have been filed at the Building Department for a seven and eight-story brick hospital for children to be erected in New York City, at a cost of \$50,000.

Appointment of Dr. Theodore Walser.—The New York Board of Health has appointed Dr. Theodore Walser, of New Brighton, the oldest physician on Staten Island, sanitary superintendent for the Borough of Richmond, to fill the vacancy caused by the death of Dr. John L. Feeny.

For University of Buffalo Alumni.—The Medical Department of the University of Buffalo announces that a "Pan-American Bureau of Information" for use of alumni exclusively has been established by the Faculty and Alumni Association. The office is located at 24 High street, Buffalo, in the library of the University Building. The bureau provides for accommodations, in advance if desired, and attends to mail, information, etc., all gratis.

A New Tenement Law in New York City.—The Health Department of New York City has issued and distributed the following circular letter: "A tenement house shall be subject to a fine of \$1000 if it or any part of it shall be used for the purpose of a house of prostitution or assignation of any description, with the permission of the owner thereof or his agent, and said penalty shall be a lien upon the house and the lot upon which the house is situated. A woman who resides in or commits prostitution in a house of prostitution or assignation of any description in a tenement house, or solicits any man or boy to enter for such purpose a tenement house, shall be deemed a vagrant and upon conviction, shall be committed to a county jail for a term not exceeding six months. If a tenement house is used for the purpose of prostitution or assignation or any part thereof, with the permission of the lessee or his agent, the lease shall be terminated at the election of the lessor. A tenement house shall be deemed to have been used with the permission of the owner and lessee if summary proceedings for the removal of the tenants of so much thereof as is unlawfully used shall not have been commenced within five days after notice of such unlawful use served by the Department of Health. Whenever the liens upon a tenement house shall amount to \$1000 or over, the Department of Health shall appoint a receiver of the rents and profits of said property."

NEW ENGLAND.

Donation to Harvard.—J. Pierpont Morgan has promised to build three of the five buildings desired by Harvard Medical School, at a cost of a million dollars. The buildings are to be devoted to biological research.

WESTERN STATES.

College of Physicians and Surgeons, of Chicago.—We are informed that the damage done to the College of Physicians and Surgeons in Chicago which was recently struck by lightning, as mentioned in the Philadelphia Medical Journal

of June 29, in no way interferes with the work of the college. The college has just obtained possession of a very large building adjacent to it, formerly the West Division High School property which it has recently purchased, and it was able to continue the operation of its summer course without interruption, by transferring its students to the new building. The building which was struck by lightning was not seriously damaged below the fourth floor, and it will be in better condition than ever by the beginning of the next fall term.

A New Publication.—*The Family Doctor* is the name of a new publication that has just been published. The editor is Dr. John L. Short, of Oklahoma City. This little journal is written for the laity, and is intended to instruct them what to do in case of accidents.

Changes in the State Charitable Institutions of Illinois.—The following changes have been made in the State Charitable Institutions of Illinois: Dr. Joseph Robbins, of Quincy, becomes superintendent of the Central Hospital for the Insane at Jacksonville. Dr. F. C. Winslow, formerly at Jacksonville, becomes superintendent of the Hospital for the Incurable Insane at Bartonville, Peoria. Dr. Samuel H. McLean, of Hillsboro, becomes superintendent of the Institution for Feeble Minded Children at Lincoln. Dr. W. E. Songer has been appointed superintendent of the Asylum for the Criminal Insane at Chester. Dr. J. C. Corbus remains superintendent of the Eastern Hospital for the Insane at Kankakee. Dr. R. F. Bennett remains superintendent of the Southern Hospital for the Insane at Anna. Dr. F. S. Whitman remains superintendent of the Northern Hospital for Insane at Elgin. Dr. W. E. Taylor remains superintendent of the Western Hospital for the Insane at Watertown.

Chair of Anatomy at the State University of California.—A chair of anatomy has been established at the State University of California, and Dr. Joseph Marshall Flint, instructor of anatomy in the University of Chicago and a graduate of Johns Hopkins University, has been appointed to the professorship.

Dr. O. J. Veline, who has been practicing at Kirkhoven, Minn., has returned from Europe, with a degree from the Royal University of Berlin.

Dr. L. Blake Baldwin, who recently received the appointment of professor of clinical dermatology in the College of Physicians and Surgeons, of Chicago, left for Paris, where he will spend three months studying skin diseases in the larger hospitals.

Northwestern University Medical School (Chicago Medical College).—N. S. Davis, Jr., has been elected Dean, and Arthur R. Edwards, Secretary of the Faculty. Wesley Hospital, in close connection with the College, has been informally opened to the profession, and after complete equipment the formal opening will take place. The Hospital will accommodate three hundred patients. Plans are completed and the money is raised for a Twenty-two Thousand Dollar amphitheatre and operating rooms at Mercy Hospital, with a seating capacity of four hundred. Drs. C. L. Mix and P. T. Burns have been appointed Assistant Professors of Anatomy.

The South Dakota Medical Society at their recent meeting in Huron, decided to meet next year in Scotland, South Dakota, and elected the following officers: Dr. C. C. Cross, of Yankton, president; Dr. Dugent, of Springfield, and Dr. B. A. Bobb, of Mitchell, vice presidents; Dr. J. L. Stewart, of Irene, secretary and treasurer; Dr. H. B. Scofield, of Scotland, assistant; Dr. H. E. McNutt, of Aberdeen, and Dr. Brown, of Parkston, trustees.

Dr. Robinson Resigns.—Dr. John A. Robinson has resigned the Assistant Professorship in Medicine in Rush Medical College.

Chicago Society of Internal Medicine.—At the annual meeting, held June 27th, the following officers were elected for the ensuing year: President, Dr. Edward F. Wells; Vice-President, Dr. George W. Webster, Secretary, Dr. Robert B. Preble; Treasurer, Dr. M. L. Goodkind; Censor, Dr. John M. Dodson.

The Medico-Chirurgical Medical College and the Columbian Medical College, both of Kansas City, Mo., recently consolidated their interests and are now building a new college.

SOUTHERN STATES.

Negro Physicians Organize.—Fifteen negro physicians organized the McRoo-Chirurgien Association of Mississippi, at Jackson, Miss., on May 17. In the past thirty years six medical schools for negroes have been established, and a total of 941 graduated students has been the result.

Recreation Building for the Insane.—The trustees of the Sheppard and Enoch Pratt Hospital for the Insane in Maryland will erect a recreation building for the use of the patients at a cost of about \$15,000.

The University of the South.—The new addition to the medical building at the University of the South, located at Seawater, Tenn., gives a seating capacity in the amphitheatre of 250, enlarges the chemical laboratory and adds a complete new lecture room and doubles the floor space in the dissecting rooms. The pathological and bacteriological laboratories have added a new equipment and the pharmaceutical laboratory has moved into new quarters. The present year promises to be the most prosperous in the history of the college.

CANADA.

Ontario Medical Association.—The twenty-first annual meeting of the Ontario Medical Association was held in the Educational Department, Toronto, on the 19th and 20th of June, 1901, the president, Dr. Angus McKinnon, of Guelph, in the chair. The secretary read the minutes of the last session of last year, which were adopted.

The report of the committee on Papers was presented by Dr. MacNeill, of Toronto, and the report of the Committee on Arrangements by Dr. Bruce L. Riordan.

Three Recent Gall-Stone Cases.—Dr. Wm. Oldright, Toronto, said these cases had occurred recently in his practice. They present features of interest to the profession. The first case occurred in a woman about fifty-five years of age. He was rather surprised to be called upon to see her in a hurry, to find symptoms of gall-stone obstruction. The late Dr. Little had seen the patient and had endeavored to obtain purgation without effect. Powerful cathartics were unavailing. About nine months previous she had a similar attack, but Dr. Oldright had heard nothing about it until this attack. The symptoms were somewhat elevated temperature (about 100 to 101), constant vomiting, obstruction, and, of course, intense pain. He supplemented Dr. Little's catharsis, but without any effect. On examination he could map out a distinct tumor, and told her that she had a distended gall bladder; he advised her to go into the hospital, which she did that night. She was operated on in the afternoon, and removed some gall-stones and endeavored to establish patency of duct. He could feel no stones left behind, but there was some stenosis of the duct. There was a great deal of inflammatory action in this case. The gall bladder was stitched into the abdominal wall and drainage established in the usual method; bile flowed freely. The patient made a good recovery. The second case was one Dr. Oldright saw in consultation with Dr. McLean, of Woodbridge. She was sixty-five years old. The prognosis was certain death without operation, and provided there was no malignant trouble she would probably recover. In this case one could imagine the difficulty there would have been had it been his first case of operation, as he could not locate the gall bladder. He came to the conclusion that it was not a case for further interference. Within twenty-four hours she succumbed to the shock and probably to some hemorrhage. There was no doubt after passing the finger in that it was malignant. If this woman had been operated on some years before, Dr. Oldright thought that malignancy would not have occurred and her life would have been saved. The third case occurred in a woman forty years of age. Upon her the surgeon operated last February. Here was a case in which there had been gall-stone symptoms, obstruction, for about eighteen months. She consented to an operation. The obstruction was in the cystic duct. He opened the gall bladder and took out the stones which he exhibited to his audience. The operation occupied about forty minutes. The patient made an uneventful recovery, and left the hospital thirteen days after the operation.

Excision of Upper Jaw for Sarcoma—with exhibition of patient and specimen.—Dr. Herbert A. Bruce, Toronto, presented this paper, whilst Dr. G. Silverthorn exhibited

the specimen. Dr. Bruce also presented the patient, a woman thirty-four years of age, from whom he had removed the upper jaw for sarcoma. The patient had been sent to him by Dr. Bowles, of Woodhill. The history of the patient is, briefly, as follows: During the last week of January of this year she felt, for the first time, a slight swelling over the alveolus of the left jaw, which she thought to be a gum-boll. She consulted Dr. Bowles at the end of March, and Dr. Bruce saw her about the middle of April—that is, less than three months after the first symptoms. Dr. Bruce operated upon her on the 29th of April, exactly three months after she had the first symptom. On examination he found a very hard swelling just behind the second bleuspid tooth and extending backwards to the full extent of the jaw. Internally it had not extended to the middle line and bulged externally to the extent of half an inch beyond what would be the line of the teeth. It extended backwards toward the antrum, but the latter did not seem to be implicated externally. The growth in the roof of the mouth was covered by a mucous membrane. On looking into the nose a polypoid mass was seen, and the patient had some difficulty in breathing through the left nostril. The cheek on the affected side was slightly more prominent, and it moved freely over the growth. No prominence of the eye on the affected side was to be made out. A small portion of the growth was removed under cocaine, and Dr. Silverthorne reported to Dr. Bruce that it was sarcoma. The patient left the hospital on the 18th of May and made an uninterrupted recovery.

Dr. Silverthorne presented the specimen to the members of the Association. It was the size of a large-sized orange, containing spindle cells with a cartilaginous basis.

Dr. Bruce stated that the history of the patient showed that a polypus had been removed about eight years ago, and he thought that it must have been a simple polypus.

Ectopic Gestation.—Dr. R. W. Garrett, Kingston, extended his thanks to the Committee on Papers for placing under his care a subject of such great magnitude. The subject is one of vital importance to every practitioner, for at any time he might be called upon to differentiate the condition from others with which it might be confounded. The responsibility of a life was in his hands and demanded accurate diagnosis, medical acumen and judgment and ability to conduct the case to a favorable termination. He entered at considerable length as to the causation and earlier changes consequent upon ectopic gestation, and stated that every physician is expected to make a correct diagnosis of tubal pregnancy on the occurrence of rupture; and in a fairly large proportion of cases, to make a diagnosis before the occurrence of the rupture. Theoretically, the arrest of a fructified ovum may occur first in the ovary; second, in the abdominal cavity between the ovary and tube; third, within the tube; and fourth, between the tube and the uterus. He would direct the attention of his audience to but one kind only; arrest within the tube, or tubal pregnancy, as all other varieties are but merely developments of this kind, owing to secondary invasion of the Fallopian tube. These he divided into three groups: First, tubo-abdominal, or simply abdominal pregnancy, in which there is a secondary invasion of the abdomen; second, tubo-ligamentary in which there is a secondary invasion of the broad ligament and sub-peritoneal tissues, and, third, that sub-division of the tubo-uterine in which there is rupture into or secondary invasion of the uterus. At considerable length he discussed the etiology, then the symptoms, pointing out the difficulties that lie in the road to making a diagnosis owing to the absence of many, if not all, of the classical symptoms generally enumerated. Having dealt in a masterly manner with these he recited a very interesting case in illustration of his contention of the difficulties of diagnosis.

MISCELLANY.

Dr. Agramonte has been appointed Professor of Experimental Pathology in the University of Havana.

Obituary.—Dr. Charles E. Pinkham, at Sacramento, Cal., on June 20, aged 62 years—Dr. John Curwen, at Harrisburg, Pa., on July 2, aged 80 years—Dr. Thomas Taylor, at Leesdowntown, Va., on July 1, aged 67 years—Dr. Charles A. Leuthstrom, at Hartland, Wis., on July 2, aged 83 years—Dr. Henry M. Revell, at Annapolis, Md., on July 3—Dr. Laurence S. Smith, at Haverhill, Mass., on July 2, aged

49½ years—Dr. James H. Conway, at North Seltuate, Mass., on July 2, aged 17 years—Dr. Edmund Weston, at Washington, D. C., on July 4, aged 71 years—Dr. J. William Stokes, at Orangeburg, S. C., on July 6—Dr. J. W. Watt, at Lafayette, Ore., on July 6—Dr. A. C. Isaacs, at Rockdale, Tex., on July 7—Dr. Frederick F. Diether, at Baltimore, Md., on July 8, aged 79 years.

Changes in the Medical Corps of the Navy, Week Ending July 6, 1901.

SURGEON T. A. BERRYHILL, detached from the Naval Laboratory, Brooklyn, N. Y., and granted sick leave for three months—June 29.
ASSISTANT SURGEON J. H. IDEN, detached from the Naval Hospital, Chelsea, Mass., and ordered to the Lancaster, July 8—July 3.
ASSISTANT SURGEON G. L. ANGENY, detached from the Lancaster and ordered to the Naval Laboratory, at Brooklyn, N. Y., July 8—July 3.

Official List of the Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Hospital Service for the 7 Days Ended July 4, 1901.

G. W. STONER, surgeon, granted leave of absence for 30 days from August 3—July 2, 1901.
J. J. KINYOUN, surgeon, directed to proceed to Yokohama, Japan and Hongkong, China, as inspector—June 28, 1901. Granted leave of absence for 4 months upon completion of duty as inspector—June 28, 1901.
J. B. GREENE, passed assistant surgeon, granted leave of absence for 2 days from July 5—July 2, 1901.
Hill Hastings, assistant surgeon, granted leave of absence for 2 months from July 15—June 28, 1901.
H. B. PARKER, assistant surgeon, relieved from special temporary duty at San Francisco, Cal., and directed to rejoin station at New Orleans, La.—June 29, 1901.
W. C. BILLINGS, assistant surgeon, relieved from duty at Baltimore, Maryland, and special temporary duty at San Francisco, Cal., and directed to proceed to Los Angeles, Cal., and assume temporary command of the service during the absence of medical officer in command, reporting to him for duty upon his return to station—June 29, 1901.
Dunlop Moore, assistant surgeon, relieved from duty at Port Townsend quarantine, Washington, and directed to proceed to Nome, Alaska, for special temporary duty—July 1, 1901.
CARROLL FOX, assistant surgeon, relieved from duty at Portland, Oregon, and directed to proceed to Port Townsend quarantine, Washington, and report to medical officer in command for duty—July 2, 1901.
G. C. ALLEN, hospital steward, relieved from duty at Mullet Key, Fla., and directed to proceed to Norfolk, Va., and report to medical officer in command for duty—June 29, 1901.
F. H. PECK, hospital steward, relieved from duty at New Orleans, La., and from special temporary duty at San Francisco, Cal., and directed to proceed to St. Louis, Mo., and report to medical officer in command for duty and assignment to quarters—June 29, 1901.
W. C. PHILLIPS, hospital steward, directed to proceed to Chicago, Ill., and report to medical officer in command for duty and assignment to quarters—May 15, 1901.

APPOINTMENT.

W. C. PHILLIPS, of Iowa, appointed junior hospital steward in the U. S. Marine Hospital Service—May 15, 1901.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended July 6, 1901.

GREAT BRITAIN.

Dr. F. Dwyer has been recently made Professor of Surgery in Dublin University.

Honored by the Pope.—The Pope has conferred the Cross "Pro Ecclesia et Pontifice" upon Mr. Francis Murphy, L. R. C. P., L. R. C. S., Edin., of Tottenham, England, who, as medical officer, was one of the gentlemen who took an active part in the great Jubilee Pilgrimage to Rome last year.

Harben Medal for Professor Koch.—Professor Koch is to be presented with the Harben Medal on Wednesday, July 24th, on which occasion a dinner has been organized to take place at the Whitehall Rooms, Hotel Metropole, London, which many distinguished member of the medical profession have promised to attend.

Foreign Obituary.—Surgeon-Captain Welford, of the 7th Battalion Imperial Yeomanry, in South Africa, on May 30—Dr. F. W. Warrington, J. P., at Congleton, Cheshire, England, on June 7, aged 62 years—R. Pritchard Roberts, M. R. C. S. Eng., L. S. A. at Bethesda, N. Wales, on June 17, aged 45 years—Dr. John Jones Ross, at Quebec, Canada, aged 68 years—Dr. Arthur A. Corte, at Eldon Place, Preston New Road, England, on June 14, aged 68 years—Dr. E. B. de la Cherois, at Brighton, England—Dr. John Broadbent, J. P., at South Collingham, England, aged 76 years.

The Sale of Poisons by Medical Men.—A meeting of medical practitioners was held in Glasgow on June 19th, to receive a report from the deputation recently sent to the General Medical Council in regard to the sale of poisons in

open surgeries by assistants not qualified under the Pharmacy Act. It will be remembered that the Council declined to receive the deputation on the ground that it proposed to deal with questions still *sub judice*. The deputation therefore had no report to make other than to repeat the decision of the Council as this was expressed in the statement made by Sir William Turner. Dr. W. Watson, who presided over the meeting and who was a member of the deputation, stated that the result of their action was in all respects satisfactory. They had succeeded, he considered, in getting the action of the Council into line with the law of the land and he felt certain that no charge similar to the one which gave rise to their action would ever again be brought against a member of the profession so long as he showed reasonable care in the management of his business. Professor Glaister, however, doubted if this consolatory conclusion was altogether justified. The finding of the Council by no means showed that the question was finally settled, but rather indicated the probability of further developments. After some discussion it was decided to continue the committee with instructions to take action if circumstances rendered this necessary. The question was also referred to at a recent meeting of the Pharmaceutical Society in Edinburgh, when the chairman claimed that the General Medical Council had decided that any medical practitioner who habitually left an open surgery stocked with scheduled poisons in charge of an unqualified assistant was liable to be judged guilty of conduct infamous in a professional respect.—*The Lancet*.

CONTINENTAL EUROPE.

University of Moscow.—At the University of Moscow, Dr. Gulewitsch has been made Professor of Medical Chemistry. Dr. Karusin has been made Professor of Anatomy.

Dr. A. Solowjew has been appointed Professor of Obstetrics and Gynecology at the University of Dorpat.

Dr. H. Sachs has been appointed extraordinary Professor at the University of Breslau.

Dr. van Walsen has been made Professor of Pathological Anatomy at the University of Leyden.

Dr. Chantemesse has just been elected a member of the French Academy of Medicine, and Dr. Heurtreaux, of Nantes, an associate member.

Dr. Monnier has been appointed Professor of Hygiene and Medical Jurisprudence at the University of Nantes, to fill the place of Dr. Olive, resigned.

Dr. Tichomilow, of Moscow, and Dr. Schaer, of Strassburg were elected foreign correspondents at the last meeting of the French Academy of Medicine.

Dr. Landouzy, now Professor of Therapeutics at the University of Paris, will become Professor of Clinical Medicine upon the retirement of Professor Jaccoud in November.

Dr. Megevand has been appointed Professor of Medical Jurisprudence at the University of Genoa.

Dr. Photinos Panas, of Paris, has been obliged to give up his chair of Ophthalmology, on account of the state of his health. Dr. Lapersonne, of Lille, has been appointed to succeed him.

The Microbe of Syphilis.—It is stated that Professor Jullien, one of the surgeons of the St. Lazare Hospital, Paris, has announced to the Academy of Medicine that he and M. Justin Bellisle have discovered the microbe of syphilis.

Gold Medal for Dr. Porro.—On May 21, at the twenty-fifth anniversary of the day, when Eduardo Porro, of Paris, performed for the first time the operation that bears his name, which was recently held, his friends and pupils celebrated the occasion by presenting him with a gold medal.

Accident to Prof. Virchow.—While out walking Prof. Virchow was blown by a strong wind against a tree and sustained an injury to the head. Assistance was quickly obtained and the Professor was taken home in a carriage. Surgical aid was provided and it is stated that there is no reason for any immediate anxiety.

Prevention of Rabies.—No case of rabies has been known in Berlin since 1873 in which year a law was passed compelling the muzzling of all dogs during the entire year.

LEWIS MARSHALL.

1.—Malins remarks that it is self evident that the art of midwifery took its rise and is coeval with the history of mankind. The concurrent testimony and allusion of all the older authors render it indisputable that women were in commencement the chief if not the sole practitioners in midwifery, and that they likewise exerted the privilege of treating the disease peculiar to their sex as well during the pregnant and puerperal state as at other times. The author gives an interesting résumé of the history of midwives in ancient and modern times. He remarks that it was the introduction of the midwifery forceps which brought about the most marked changes in practice and the direst revolution among the midwives. He urges the adoption of a code of rules for the regulation of the practice of obstetrics by midwives. He claims that England is far behind the other nations in this respect. [W. A. N. D.]

2.—C. H. Milburn in this address compares in an interesting and entertaining way the surgery of the time of Ambroise Paré with that of the present day. He shows that until the middle of the present century the advances in surgery had been comparatively slow. Reference is made to a number of interesting gun-shot injuries received in the South African war. [J. H. G.]

3.—Ralph Stockman reports a case of purpura rheumatica. The patient can assign no cause for the illness for which he has been under treatment in the hospital. For more than two months he has suffered from diarrhea, general weakness, a swelling in some of the joints and an eruption situated chiefly in the lower limbs. Seven years ago he had an illness which was exactly similar to this, only the attack was much lighter. Since admission to the hospital there have been 22 distinct eruptions, some much more abundant than others and chiefly on the lower limbs. The fresh spots are of a bright purplish-crimson hue, and in a day or two they become a dull red, then of a light rust color, slowly fading until they are almost imperceptible. Each outbreak of spots is preceded by pain in his large joints, so that he can foretell their occurrence. The blood examination on admission revealed 4,000,000 red cells. The hemoglobin was 66%, and the leucocytes and blood plates were normal in number. The temperature has been mostly subnormal—97 to 98°, but on five different occasions it has risen in the early evening to 101° or slightly over. The red corpuscles in this case were normal in size and shape, but did not form rouleaux. When a large drop of fresh blood was allowed to fall on a microscope slide, it clotted in the same time as a drop of blood from a healthy person, but granules formed in it which were readily visible to the naked eye, and under the microscope these were seen to be due to the red corpuscles having run together in irregular clumps. The treatment consisted in

confining the patient in bed and the administration of 20 grains of salicin four times a day for 23 days, then one drachm *liquor calcis saccharatus*, thrice daily for six days, then *extractum ergotae liquidum*, 20 minims thrice daily for ten days, then *oleum terebinthinae*, 10 minims four times a day for 27 days, and finally 10 grains of quinine daily for three days. In addition to this, the patient was placed on a freely digestible diet. [T. L. C.]

4.—W. D. Halliburton in his third Croonian lecture on the **Chemical Side of Nervous Activity** states that chemical pathology is a comparatively new branch of science, and he has dealt with the subject under three heads: 1. The Chemical Pathology of Hyperpyrexia. 2. The Chemical Pathology of General Paralysis of the Insane. 3. The Chemistry of Wallerian Degeneration. As to the first head, the experiments may be summed up by saying that they fully confirm the hypothesis that the physico-chemical cause of death from hyperpyrexia is heated coagulation of cell globulin. When this constituent of cell protoplasm is coagulated, the vitality is destroyed. The temperature at which such coagulation is most readily produced is 47° C. Although the nerve cells are those which lend themselves most readily to the histological part of the research, it is by no means improbable that many other cells of the body are affected by high temperatures in a corresponding manner; some varieties are without doubt instances of coagulation necrosis. Researches of Halliburton under the second head, the **Chemical Pathology of General Paralysis of the Insane** have been published previously. The cerebro-spinal fluid removed from cases of general paralysis of the insane, is much increased in quantity and takes the place of atrophied brain material. On injection into the circulation of an anesthetised animal, a fall of arterial pressure with little or no effect upon respiration is observed. This fall of pressure is due to an organic substance which is soluble in alcohol. This substance is precipitable by phospho-tungstic acid, and by chemical methods and was identified as **choline**. The crystals of the platinum double salt which, when crystalized from 15% alcohol, are characteristic octahedral, or the most convenient test for the separation of this base. Normal cerebro-spinal fluid does not contain nucleo-proteid and the amount of choline is so small that it cannot be readily identified. It produces no effect upon arterial pressure. Nucleo-proteid and choline doubtless originate from the disintegration of the brain tissue, and their presence indicates that possibly some of the symptoms of general paralysis may be due to auto-intoxication. The proof that the toxic material is choline has been attested by physiological experiments. The action of the cerebrospinal substance exactly resembles that of choline. **Neurine**, an alkaloid closely related to choline is not present in the fluid. Its toxic action is much more powerful, and its effects differ considerably from those of choline. Our knowledge of the chemistry of nerve degeneration (Wallerian) is limited to what occurs in lecithin, the main constituent of myelin. This substance is broken up in its constituents and each of these is in time removed by absorption. The products of disintegration are four in number: **Choline, Phosphoric acid, fatty acid and Glycerine**. [T. L. C.]

5.—G. A. Peters describes a case in which he first operated for **procedentia recti** and subsequently for **extrophy of the bladder** in the same patient. The first operation was done when the child was 2 years and 7 months old. The prolapse of the rectum extended for 4½ inches and during crying or during the act of defecation the protrusion measured 8 inches. There seemed to be no hernia occupying the peritoneal *cul de sac*. For the relief of this condition the abdomen was opened in a median line and the bowel easily drawn into the pelvic cavity. A fold was then made in the anterior wall of the rectum by placing two rows of Lembert sutures. The rectum was then fixed to the anterior abdominal wall. The extrophy of the bladder was operated upon after a unique method. The rectum

was first thoroughly cleansed and a sterile sponge carried well up into the bowel to prevent any fecal matter from coming down. A small catheter was then placed into each ureter and fixed. The ureteral orifice with a portion of the mucous membrane was then separated from the rest of the bladder. The rectum was then pushed forward and a small incision made on either side of this bowel. Through these openings a forceps was passed which grasped the rubber tube fixed in the ureter and drew the latter organ well into the rectum. The two tubes occupying the ureters were allowed to remain two or three days. The ureters were not sutured to the rectal mucous membrane but quickly became united. The patient made an excellent recovery and 18 months after the operation is in excellent health, there being no evidence of any rectal irritation or of kidney infection. The avoidance of entering the peritoneal cavity is the author's principal claim for this operation. [J. H. G.]

6.—Andrew Fullerton reports a case of meningo-encephalocoele in which he removed the entire tumor successfully. The patient, however, developed bronchitis after being discharged from the hospital and died from this condition four weeks after the operation, the wound having entirely healed without trouble. The tumor was situated in the occipital region and contained a portion of the brain the size of a small hen's egg. The operation was done when the child was three weeks old. [J. H. G.]

7.—Lewis Marshall recommends operation in cases of **spina bifida**, and reports several cases in which he has operated successfully. [J. H. G.]

3.—Cairns discusses the agglutinating property of blood serum in cases of plague. In preparing the emulsion of plague bacilli the author used a 24-hour culture grown upon agar. A sufficient quantity of sterilized salt solution (75%) was poured into the tubes to cover the slanted agar. The growth was rubbed off the surface of the agar slant with a glass rod, and the emulsion was then decanted into a sterilized test-tube. The emulsion of plague bacilli prepared by this method yielded a homogenous and workable mixture which remained unchanged for about 24 hours. Upon microscopical examination the bacilli were found perfectly free in this fluid, and were not grouped together in clumps. The blood was collected in Pasteur pipets about 30 centimeters in length. After collecting the blood the pipet was set aside in a cool place for several hours, until the serum had separated. Test-tubes, about 9 centimeters in length and about .7 of a centimeter in diameter, were found most convenient in the technique of the macroscopical method. These test-tubes were sterilized at a temperature of 160°C. for one hour. The tubes were plugged with cotton wool. In these investigations 5

dilution were employed, namely, 1 in 10, 1 in 25, 1 in 50, 1 in 75, and 1 in 100. Positive reactions were not obtained with dilutions higher than 1 in 75. Control experiments were employed in all instances. The author has appended a number of tables in his article, which give the results of his observations. He concludes that the reaction does not occur during the early days of the disease. It is absent in rapidly fatal cases. Towards the close of the first week of the disease, agglutinative properties show themselves; the intensity of the reaction increases up to the 6th week. After the 6th or the 8th week the serum gradually loses its agglutinative power. As a rule, the rise and the fall in the intensity of the reaction are approximately equal. In severe fatal cases the reaction never reaches a high degree of intensity, while in equally severe cases, which rapidly convalesce, the reaction is more intense. The agglutinative power of the serum in some of the mildest cases is slight and it may be absent. In severe forms of plague, in which there occurs an early and favorable crisis, the reaction is, as a rule, most marked. From a diagnostic standpoint the application of the agglutinative reaction will be found to be of great value. [F. J. K.]

4.—Hutchison highly recommends sugar-free milk as a food for diabetics. The author gives a plan of a strict diet which includes sugar-free milk. In one of his cases the patient followed this scheme. While upon an ordinary diet 300 grams of sugar were excreted daily, and when placed upon the strict diabetic diet, which consisted largely of sugar-free milk, the patient excreted only 25 grams of sugar, and gained in weight. [F. J. K.]

5.—Porter highly recommends the prophylactic administration of antitoxin in the prevention of diphtheria. He employed the prophylactic injections in 24 families during an epidemic of diphtheria with very favorable results. In only one person so injected did diphtheria develop subsequently. The injections were refused in 8 instances, and amongst these 3 afterwards developed the disease. In another series of 21 families in whom the prophylactic injections were not used, diphtheria subsequently developed in a large percentage of the individuals. The author believes that the use of antitoxin is a valuable means of preventing the development of diphtheria in persons exposed to infection. [F. J. K.]

6.—Hall-Edwards describes his experience in South Africa with the X-rays. In all he examined 193 cases of gun shot or shell wounds and in 65 the missile was located by the rays and subsequently removed. The large majority of bullets removed were found between the ankle and the abdomen while the upper extremities with the exception of the hands were comparatively free. The author compares the use of the X-ray for the purpose of locating bullets with the older methods of probe, etc. [J. H. G.]

7.—Wright and Wrigley report a case of aneurysm of the subclavian and axillary arteries occurring in a man 36 years of age. The first symptoms were noticed six months before operation and the patient's occupation, which required the lifting of heavy sacks of flour, was supposed to have been an etiological factor in the case. The subclavian artery was exposed and as its second division was found to be healthy two large silk ligatures were placed about it. The wound healed primarily, the dressing not being removed until the 11th day. At the time of the patient's discharge from the hospital there had been no return of the radial pulse but the extremity was well nourished. A faint pulse was perceptible about two months after the operation when the aneurysm was found greatly contracted and hard, presenting no pulsation. [J. H. G.]

8.—Itote writes upon the values of meat preparations and the possibility of myosin albumin. He contends that extractive compounds are of little value except for their excitatory properties. From a dietetic standpoint the value of gelatin is still an unsettled question. He highly recommends albumins and concludes that the field of usefulness open to myosin albumin is a wide one. The method of procuring a suitable, cheap, and economical process for extracting myosin albumin still remains unsolved. [F. J. K.]

9.—Clarke gives the notes of a case of fibroma of the lesser omentum. The tumor was situated obliquely in front of the stomach. Just behind the growth lay the pylorus. The tumor received its blood supply from the gastroduodenal portion of the hepatic artery. [F. J. K.]

MEDICAL RECORD.

July 6th, 1901.

1. Observations in China and the Tropics on the Army Ration and the Post Exchange or Canteen.

MAJOR LOUIS LIVINGSTON SEAMAN.

2. The Place of Cereals in Infant Feeding.

HENRY DWIGHT CHAPIN.

3. The Value of Local Sanatoria in the Combat of Tuberculosis in Large Centers of Population.

S. A. KNOPF.

4. Observations and Remarks on Removal of the Gas-serian Ganglion in the Cadaver. ROBERT A. AMYX.

5. Primary Carcinoma of the Tip of the Appendix, etc. J. RIDDLE GOFFE.

1.—Major Lewis Livingston Seaman, late Surgeon to the 1st U. S. Volunteer Engineers, presents an interesting paper on: Observations in China and the Tropics, on the Army Ration and the Post Exchange, or Canteen. He gives a most interesting description of the U. S. Military Hospital in Peking, a portion of which, Camp Riley, occupies one of the many compounds of the Temple of Agriculture, one of the most sacred and classic spots in the celestial empire. He draws a favorable comparison of the health of the American troops compared with those of other nations, and especially in the freedom of our troops from enteric fever. This would indicate, as the writer points out, that we have profited by our experiences of the Spanish-American War. He narrates the great improvement in health which took place among our troops in the cold and invigorating climate of Peking in contrast with their run-down condition upon arriving from the Philippines, and attributes this in no small part to the excellent food which the soldiers received. He makes a strong plea for the re-establishment of the canteen. [T. L. C.]

2.—Henry Dwight Chapin of New York, discusses the place of cereals in infant feeding, and states that chemical analyses of milk are not the only scientific basis of comparison; that nature adapts an animal's milk food to its digestive system, and that cow's milk and woman's milk were intended for different digestive systems; that as cows milk forms solid curds, and woman's milk flocculent curds, the curd of cow's milk intended for an infant should be broken up mechanically, that as cereal gruels mechanically break up the curds of cow's milk, and as infants are able to utilize them, their use is rational. Chapin believes that it is often preferable to make a standard diluent of digested gruel, as they not only break up the curds but expose a surface of milk proteins and not starch, and furnish a certain amount of nourishment, that is at once available for carrying on the work of digestion, taking the place of part of the soluble proteins, and also form a satisfactory substitute for milk when it must be withheld for a few feedings. [T. L. C.]

3.—S. A. Knopf, in a lecture upon the value of local sanatoria in the combat with tuberculosis in large centers of population, emphasizes his well known views upon the great importance of this form of treatment. Consumption can be prevented by proper sanitation, training and education. It can be cured in nearly all climates by proper hygienic and dietetic treatment under constant medical supervision, at home or in the sanitarium. [T. L. C.]

4.—Robert F. Amyx contributes an exhaustive paper on "Observations and Remarks on the Removal of the Gas-serian Ganglion in the Cadaver." He emphasizes especially the importance of careful dissection of the ganglion from the dura and other contiguous structures, the dissection being made upon the ganglion and its branches as much as possible. This method of attack will prevent profuse hemorrhage. The ganglion must be dissected from its dural covering, the cavernous sinus, internal carotid artery and middle meningeal artery before any effort is

made to remove it. Observing the caution given above in carrying on the dissection upon the ganglion and its branches will be especially important in preventing the occurrence of hemorrhage. [T. L. C.]

5.—J. Riddle Goffe reports two rare cases of primary carcinoma of the tip of the appendix, primary epithelioma of the sphincter muscle of the bladder. These two cases are unique in demonstrating the presence of primary carcinoma in most unusual locations. It is significant too that they were discovered in two unmarried women, and both at so early an age. The patient with the cancer of the appendix being but 15, and that of epithelioma of the sphincter muscle of the bladder but 28. [T. L. C.]

NEW YORK MEDICAL JOURNAL.

July 6, 1901. (Vol. LXXIV, No. 1.)

1. Chronic Fluorine Poisoning. FRITZ SCHWYZER.

2. The Limitation of Drug Therapy.

ROBERT H. BABCOCK.

3. Remarks on Appendicular Abscesses.

RAMON GUITERAS.

4. An Improved Form of Ambulance would Increase the Value of the Treatment of Ileat Prostrations.

FREDERICK GRIFFITHS.

5. Puerto Rico; its Climate and its Diseases.

C. H. ALDEN.

6. Letter from Toronto.

1.—In chronic fluorine poisoning, F. Schwyzer points out the fact that fluorine is capable of a cumulative action under certain conditions. In small doses it is a relatively harmless preservative agent; but as soon as it is given a chance to accumulate in the body through continued administration, it becomes dangerous, and its employment should be prohibited by law. This applies especially to beverages and food stuffs that are consumed regularly and in large quantities, particularly beer, green vegetables, milk and meat. Great caution should be exercised in prescribing fluorine for internal use. Especially in recent years, numerous fluorine preparations have been recommended for the treatment of consumption always accompanied by the assertion that they are positively non-toxic. There is no doubt in the author's mind that poisoning can also be produced by organic fluorine combinations, if used too long. It is particularly necessary to draw attention to this latter fact, as the symptoms of fluorine poisoning are not very pronounced, and it is rather difficult to detect the fluorine in the body. [T. M. T.]

5.—C. H. Alden, in his article on Puerto Rico, its Climate and its Diseases, gives the following diseases as prevalent on the island: The highest death rate is from anemia, or "tropical chlorosis," with during the last ten years an average of 4513 deaths out of 27,915 deaths yearly. Intestinal diseases are quite common. In the last ten years the death rate was 1183, or 3.83% of the total deaths. Malarial fevers are much less prevalent in Puerto Rico than in Cuba, and during seven months ending April 30, 1900, 1514 deaths, or 6.32%, from these fevers were reported, but it is most likely that the diagnosis was incorrect in many cases. Yellow fever is not endemic. Typhoid fever averages 383 deaths, or 1.43%, annually of the total number of deaths. Malaria fever is thought to be responsible for many cases of fever of the irregular course and is endemic. Tuberculosis, presumably almost entirely pulmonary, gives an average of 1824 deaths yearly, or 6.78% of the total deaths. Tetanus is frequent and fatal, there being an average of 952 deaths, or 3.57% of the total deaths. Venereal diseases, especially syphilis, are very common in the lower classes. There is also a very large proportion of blind in Puerto Rico which is largely due to ophthalmia neonatorum and small pox—the ratio being about one in every 480 persons. Small pox causes about 623 deaths annually, the highest number

being 2362 in 1899, the lowest 11 in 1893. Cerebrospinal meningitis causes quite a number of deaths—from 1899 to 1899, 395, or 1.12% of the total deaths. Leprosy exists, of which the tubercular form is the usual one. Elephantiasis is quite common and has often been mistaken for leprosy. [T. M. T.]

MEDICAL NEWS.

July 6, 1901. (Vol. LXXIX, No. 1.)

1. Practical Notes Relative to Rabies. N. G. KEIRLE.

2. Actinotherapy in Cutaneous Medicine, a Preliminary Communication. WILLIAM S. GOTTHEIL.

3. Ideals in Physical Education. D. A. SARGENT.

4. The Early Operative Treatment of Acute Mastoid Inflammation. EDWARD B. DENCH.

5. Salient Points in an Epidemic of Typhoid Fever Based upon Fifty-five Cases. WILLIAM J. CRITTENDEN.

6. A Case of Lobar Pneumonia with Hyperpyrexia; Recovery. WILLIAM R. WILLIAMS.

1.—N. G. Keirle divides his article into three divisions: (1) At what times and under what circumstances should patients be advised to submit to treatment; (2) With what material and in what manner are they treated; (3) What risk attends treatment? Under the first condition, the author states that the treatment must be commenced immediately, even if we are not sure that the dog is mad. The dog must never be killed, and if, after being observed daily for a few days, he shows no sign of rabies, the treatment may be discontinued. He reports three cases in which the delay was considerable, all of which developed rabies about the same time as the animal that was inoculated. However, a number having no treatment escaped. The material used is not a serum, but a portion of the spinal cord of a rabbit that has died of rabies. This is rubbed up in sterile cool water. The spinal cords are dried over caustic potash, which diminishes the amount of virus, but does not attenuate it. The method is subcutaneous hypodermic injection in the abdominal region. There is no risk greater than the rare and unjustifiable occurrence of abscesses. Lumps caused by proliferation of connective tissue are common, as is also a local or general erythema. Treatment must be continued for at least 23 days. [T. M. T.]

2.—W. S. Gottheil, in his article on actinotherapy in cutaneous medicine, gives the following advantages of the methods: First and foremost, it is eminently conservative. It causes no radiodermatitis, ulceration, or loss of hair, such as too often, though sometimes necessarily, occur under the Roentgen treatment. The author knows of no record of any serious trouble following its employment. Finsen rightly lays stress upon this point; and to dermatologists it is of special importance, since many of the affections that they are called upon to treat occur upon the face. In the second place, it is entirely painless. This is a great desideratum, more especially in dealing with women and children. Third, it is effective. New as the method is, there is already concurrent testimony from a sufficient number of competent observers to demonstrate that we possess a powerful therapeutic agent in concentrated light. [T. M. T.]

4.—E. B. Dench recommends in his article on mastoid inflammation opening the antrum and establishing a free communication with the middle ear. If this is done, the operator can thoroughly remove every focus of infection without running the risk of invading some important region. It must be remembered that even in cases where the examination reveals only slight mastoid involvement, the inflammatory process may have been so extensive as to have already invaded the lateral sinns, which it is important to ascertain. Another reason is that a large opening in the bone enables one to determine whether or not any intracranial inflammation is actually present. [T. M. T.]

1.—Davis delivered the annual address, entitled "Poverty and Degeneracy; their cause, prevention, and cure," before the American Medical Temperance Association, at St. Paul, on June 6, 1901. The author states that there is ample statistical and experimental evidence to show that alcohol leads to slow tissue degeneration, and renders individuals susceptible to acute infectious diseases. He emphasizes that alcoholic liquors are undoubtedly responsible for a large percentage of both physical and mental degeneracy. He points out that alcoholic drinks, tobacco, and other narcotic poisons are responsible for seven-tenths of all the pauperism, crime, and degeneracy of the people of this country and of Europe. In this interesting article the author states that for every dollar received as revenue money for alcoholic liquors and tobacco, the governments and municipalities must expend \$10 for the support of the resulting pauperism, insanity, crime, and degeneracy. He argues that if alcohol and other well-known narcotic drugs are wholesome articles for food and drink, and safe for general use, the public should not be compelled to pay a special revenue tax which is now imposed upon these articles. If these substances are dangerous poisons, destroying both the public health and morals, they should be classed among the list of poisons, such as arsenic, strychnine, etc., and their sale regulated by sanitary authorities, aided by the courts. [F. J. K.]

2.—Andrews, Chairman of the Section on Stomatology, at the 52d meeting of the American Medical Association, delivered the annual address before that section. In this discourse he reviewed the more important events which presented themselves during the year, especially those pertaining to dental education. [F. J. K.]

3.—Card discusses the appointment of a State Board of Medical and Dental Examiners. He emphasizes that as appointments are often made for political and personal reasons, unfit and unsuitable boards result. He believes that the system of controlling education in the State of New York by the Board of Regents, is by far the best that now exists, and hopes that the education of every other State in the Union will be regulated by a similar body. [F. J. K.]

4.—Parmele believes that the revenue for the maintenance of the State Board of Dental Examiners should be collected from the candidates presenting themselves for examination. [F. J. K.]

5.—Turner discusses the methods for collecting revenue for conducting the work of the Board of Dental Examiners. (1) by taxation of the people; (2) fees collected from the candidates for examination; (3) by taxation of the profession. The author contends that the most satis-

factory plan, considering all things, is to collect fees from the candidates for examination. [F. J. K.]

6.—Chittenden, in a paper read in the Section of Stomatology, discussed the Dental College standard. [F. J. K.]

7.—Libbey sets forth sufficient evidence to show that reform is needed in the system of dental education, and believes that when the people and the profession realize the state that now exists, laws will be enacted to insure against quackery. He maintains that every stomatologist should receive the degree of Doctor of Medicine. [F. J. K.]

8.—A. H. Cordier speaks of the seriousness of post-operative hemorrhage, its causes and prevention. The author has lost one case from post-operative hemorrhage, the result of the slipping of a catgut ligature, and has operated a number of times for such a condition following this cause. Oftentimes the Trendelenburg position will prevent the patient bleeding upon the table, and yet, when restored to the horizontal position in bed, bleeding may occur, particularly capillary oozing. It is recommended that a drainage tube in suspected cases be used for a few hours. In the cases seen by the author the hemorrhages occurred after simple operations. Attention is called to the difficulty which is not infrequently met with in differentiating between shock and hemorrhage, and it is in these cases that the drainage tube is of value. When once hemorrhage is suspected the abdomen should be promptly opened sufficiently to permit the introduction of a drainage tube. Salt solution introduced into the circulation has saved the lives of many cases of post-operative hemorrhage. [J. H. G.]

9.—Hunter Robb discusses the advantages and disadvantages of drainage after abdominal operations. Formerly it was his custom to employ drainage after certain abdominal operations. Gradually, however, he has abandoned the use of the drainage tube. In 222 consecutive cases only 1 was drained, a pus case where it was impossible to remove the entire abscess wall. In these 222 cases 28% were pus cases. Robb states that not only have his immediate results been better, but also his remote results since the abandonment of drainage. [J. H. G.]

10.—Gottheil defines radiotherapy as meaning the therapeutic use of the Roentgen Rays. Actinotherapy, he defines, as the employment of the ordinary sun or arc light, or portions of their rays, as therapeutic measures. The author does not agree with Flinsen who asserts that actinotherapeutic treatment requires hourly sessions every day. The author has reduced the time of treatment very materially, giving his patients only half hourly sittings every other day. He emphasizes that the length of the treatment depends largely upon the intensity and concentration of all the available actinic light. He employs an instrument manufactured by a firm in New York City, called the "Actinolyte." This instrument consists of an arc light, which can be regulated automatically, and a double convex condenser, the position of which can be regulated so that a circle of light of any size can be obtained. The heat rays are cut off by a cell which contains fluid. The author mentions that actinotherapy has proved useful in lupus vulgaris, lupus erythematosus, mycotic eczema, trichophytosis, favus, impetigo, furunculosis, tuberculosis cutis, epithelioma, mycosis fungoides, blastomycosis, actinomycosis, and other similar affections. [F. J. K.]

11.—Matthew D. Mann describes a new operation for removal of cancer of the rectum. The operation is suggested for cases where the growth is considered too high up to be easily reached through the vagina. The diseased portion of the bowel is excised and an anastomosis is made by means of the Murphy button. The author has been surprised to find with what ease this resection of the rectum can be done when the patient is placed in the Trendelenburg position. [J. H. G.]

12.—Deever emphasizes the necessity for a thorough knowledge of the pelvic viscera, their topographical relations and the pathology of their diseases in order to successfully cope with the accidents and complications of pelvic surgery. The most common of these complications is the formation of adhesions, the result of inflammatory processes involving the pelvic organs. These adhesions vary in character, some are easily separated while others are old and organized. The simple removal of the lesions is not sufficient in pelvic operations. In addition there should be thorough liberation of adhesions and the covering in of abraded or torn surfaces by peritoneum. This

may require considerable force or even division by means of the scalpel. Injury to the peritoneal coat of the bowel does not present any formidable condition, but when the muscular coat has been torn an effort should be made to suture the parts together, providing that the caliber of the bowel will not be impinged upon too much. In the same manner traumatism of the bladder must be attended to promptly. The displacement upwards to which the bladder is liable in the presence of a large growth or cyst makes it possible to injure that viscus in making the abdominal incision. Peritonitis in association with fibroids is rare in comparison to that of ovarian tumors and the inflammatory affections of the uterine appendages. In such cases, if pus be present, it is only after the most careful walling off of the peritoneal cavity that any attempt should be made to remove the uterus with its tumor. The most common complications of a rupture of an extrauterine gestation are hemorrhage, adhesion, and appendicitis. When appendicitis and extrauterine pregnancy are found together the latter usually involves the tubes of the right side. It is only in the presence of a sepsis that much danger can accrue from the combined lesion. The points where hemorrhage is most likely to take its origin are, the omentum and the ovarian, uterine, appendical, and mesenteric vessels. Postoperative peritonitis ranks highest in the fatality of pelvic operations. The treatment of a lacerated cervix calls for a great display of good judgement and skill as does any of the major operations on the pelvic viscera. [W. A. N. D.]

13.—Muscroft and Ingals give a report of a case of cirrhosis of the liver which occurred in a man, aged 45. The Talma-Morison operation was performed to give the patient relief, but death occurred 30 hours after the operation. Chloroform was used as the anesthetic; only a small amount was necessary. [F. J. K.]

7. Pilocarpin Hydrochlorate and its Use in Croup. S. E. WERTMAN.

1.—Walter Reed, James Carroll and A. Agramonte present an interesting study of yellow fever produced experimentally. In the first class of cases, the injection of the blood of a yellow fever patient induced the disease in four cases. The production of yellow fever by the injection of blood taken from the general circulation is of much interest, showing, first, that the parasite is present in the blood at least during the early stages of the disease, and secondly that the passage through an intermediate host, although this would seem to be nature's methods, is not essential in the life cycle of this parasite. In four cases the disease was produced by the bite of the infected mosquito, the *Culex fasciatus*. These latter cases were of interest, as showing the length of time during which the mosquito may remain capable of conveying the infection. Three mosquitos applied on the third day acquired the parasite and were able to infect three individuals with yellow fever. A single mosquito applied to the same case of yellow fever on the fourth day of the disease failed to obtain the parasite, as shown by the negative results 40 days after contamination. The authors submit one case in which a patient was repeatedly bitten by mosquitos who had fed upon yellow fever cases, but who were not infected. This indicates since the patient was nonimmune, that all mosquitos do not become infected. The authors' studies

upon the incubation period of yellow fever confirm a statement of later writers that it does not usually exceed four or five days, but that it may be prolonged more frequently perhaps than has been supposed. In the 12 cases produced by mosquito inoculation in the series of experiments, the onset was sudden in two and gradual in 10. In both of the former, the attack occurred during the night. The patient also in both instances being awakened by the onset of a decided chill. Of the 13 cases in which the onset was gradual, by mosquito inoculation 10; by blood injection, 3, frontal headache was the most frequent premonitory symptom. The fever charts of the cases will show that the primary rise of temperature is tolerably abrupt and reaches its height in a very short time. It does not reach its maximum as quickly as the writers would seem to indicate. The tri-hourly record in 10 of our mosquito inoculations shows that this period of primary rise varies from 12 to 24 hours. The average period was a fraction over 16 hours. In striking contrast to these was the short period of the primary rise of temperature in the four cases produced by blood injection. In these it varied from 2½ to 9 hours, the remaining two cases giving 6 to 7 hours respectively. In the 12 cases due to mosquito inoculation, the primary rise of temperature was followed by a distinct remission or intermission which was generally reached in 48 hours. The same remission was present in three of the four cases produced by blood injection. The authors believe that the facts presented, indicate that the period of inoculation of yellow fever occasionally exceeds the quarantine period of five days, and that although exceptional, this must not be left out of consideration. Secondly, their observations emphasize anew the importance of recognition by the profession of very mild cases of yellow fever so forcibly pointed out years ago by John Guiteras. [T. L. C.]

2.—Augustus Wilson presents a paper on a Medico-Legal Aspect of Tuberculous Joint Disease. He makes the observation that the law only requires a physician to do the best that he is able, and not the best that any physician might do in the treatment of a case. He mentions visiting a hospital ward devoted to children, in which 10 cases of hip-disease, all having properly applied extension apparatus, were permitted to sit up in bed. It was believed that all of the cases would have abscesses sooner or later, and all would have stiff hips and short legs. The mistake of permitting these patients to sit up would readily account for such an outcome. Unlike acute inflammatory processes, tubercular osteitis demands for its recovery perfect fixation for a long time and any attempts by movements to prevent stiffness will provide the very traumatism that is needed to maintain and increase the destructive process. The loss of joint usefulness should never be considered as a necessary or unavoidable result of tubercular joint disease, but rather as a distinct evidence of failure in not having the attention of a physician sufficiently early. Failure to reach a correct diagnosis or inappropriate forms of treatment are also responsible for untoward results. [T. L. C.]

3.—A. P. Ohlmacher reports three cases of myocardial degeneration following coronary arteriosclerosis. These conditions are illustrated by typical cases. Even at autopsy the underlying mechanism in such cases of death from "heart failure" is not always appreciated. There are examples of heart-muscle lesions, of myocardial disease, resulting from arteriosclerosis of the coronary arteries, the latter affection usually being a part of a general arteriosclerosis, and thus they represent one of the several modes by which arteriosclerosis, that peculiar disease of advanced life, brings man to an unexpected end. The first case was one of sclerosis and thrombosis of the right coronary artery with a softening of myocardium and unexpected death. The second case presented sclerosis and thrombosis of the left coronary artery with anemic softening, rupture of the heart, and sudden death. The area of

softening thus corresponds to the usual type of *myomulacia cordis* as it is the counterpart of hemorrhagic infarction in any other organ in which terminal arteries are occluded by thrombosis or embolism. The third case was one of sclerosis and obliteration of the left coronary artery with fibrous myocarditis, aneurysm of the heart, and death during pneumonia. [T. L. C.]

4.—R. T. Edes reports a case of occlusion of the vena cava from compression associated with diffuse cancer, chiefly abdominal. The report of the autopsy is included. Obstructions complete or partial of the vena cava are far from being rare. In this case it could be followed downward from the diaphragm from just below the renal veins at which point its cavity came to an abrupt ending containing a rounded mass and firmly occluding it. A résumé of some interesting cases from the literature accompanies the report. [T. L. C.]

5.—James M. Ball reports a case of *aspergillus keratitis*, a rare variety of corneal inflammation of which less than a dozen cases are described in the literature. The author believes that the condition is much more common than has been thought. He reports a case of the condition and emphasizes these points: *Aspergillus keratitis* is a more common disease than has been supposed. Intense pain in the eye, followed by the development of a brownish or black mass within the substance of the cornea are pathognomonic signs of *aspergillus keratitis*. Removal of the mass early in the case is followed by uninterrupted cure. Failure to recognize the condition and to apply proper treatment is followed by sloughing of the cornea and in some cases by the loss of the eye. In the few cases of *keratomycosis aspergillina* in which cultures have been made, only *aspergillus fumigatus* has been found. [T. L. C.]

7.—S. E. Wertman has treated a number of cases of croup, unusually severe and malignant in type, with pilocarpin hydrochlorate. Brief reports of five cases are given. He used antitoxin in three cases all of which were fatal. These cases had received in addition internal and local treatment with which up to this time he had been having good results. Five cases treated after the latter method (excluding antitoxin) recovered. In another case in which the disease had assumed such a grave form that dissolution seemed but a few hours distant, instead of giving large doses of pilocarpin hydrochlorate, the drug was administered in small doses hypodermically. As to dosage a child of four years received hypodermically, 1-32 of a grain dissolved by heat. The injections should be given some eight hours apart. [T. L. C.]

1.—The first article in this number is of such extraordinary importance that the following abstract has been made very complete.

The first positive experiment was made from the peritoneal fluid of a man 51 years of age upon whom an exploratory operation was performed August 12th, 1898. The patient presented all the signs of a large intraperitoneal tumor, and at the operation the abdominal fluid was drawn off with careful aseptic precautions into 3

test tubes and several flasks. Inoculation from this fluid upon various media was negative. Microscopical examinations showed, however, the presence of pale spherical bodies from 2 to 10 microns in diameter that resembled fat, but had too low a refractive index, did not stain black by osmic acid, and could not be extracted by ether under any circumstances. They could be stained by the usual aniline dyes, but fixation caused considerable distortion. A few of these contained granules with Brownian movements. These tubes were examined every day, and it was possible to demonstrate that the spherical bodies gradually increased in size, became more indefinite in outline and lost their yellowish green color. During this period they commonly sent out pseudopods and long projections. In some cases a delicate nucleus could be made out. Ultimately a few of them became transformed into what appeared to be large sacks containing highly refractive granular and small spherical bodies; these of course resembled a sporulation stage. This fluid was centrifugated, and from the supernatant liquid injections were made into the peritoneal cavity of a female dog and of a guinea-pig and into the jugular vein of a guinea-pig. In the meantime the patient died. An examination of the tissues showed the characteristic picture of colloid carcinoma of the peritoneum, probably originating in the appendix. The microscopical structure resembled that of adenoid carcinoma. Cultures from the tumor were entirely negative. Twelve days after inoculation the guinea-pig that was inoculated into the jugular vein, was distinctly listless. Fifty days after inoculation it was killed and examined. There was no reaction at the site of inoculation. The pleura was slightly infected and the lung contained numerous minute nodules. The other organs appeared to be normal. These nodules histologically presented the typical picture of adenocarcinoma. Sections stained by Plimmer's method showed the presence of vast numbers of the peculiar organisms described by him. Small hyaline bodies were found in the heart blood that resembled those found originally in the peritoneal fluid. In the animals that had received injections into the peritoneal cavity, when killed, a small amount of fluid was found that contained the peculiar hyaline bodies found in the original peritoneal fluid. These when placed in the thermostat went through the same cycle of changes. Cultures were attempted but were unsuccessful on account of the use of unsuitable media. In both these animals there was some indication of implication of the mesenteric lymph nodes. Gaylord then undertook the examination of a large number of tumors in order to determine whether these peculiar hyaline bodies could be found in them. These are apparently tabulated in another portion of the paper under the title of "Typical Plimmer's Bodies, Intracellular Protozoan Forms and Russell's Bodies," and he is able to state that he has found them in "all organs including the blood, taken from all regions, of all cases dying of cancer, including sarcoma and epithelioma." Moreover in "all cases of carcinoma and sarcoma thus far examined, in which cachexia was well marked, that the organism, especially the younger forms, can be detected in the peripheral blood." Gaylord now gives a résumé of the literature of the blastomycetes in relation to cancer, particularly those of Sanfelice and Plimmer. He is enthusiastic about the Plimmer's staining method, adding to it however, as a 6th stage, immersion of the section in peroxide of hydrogen until the black color is removed. In all cancers that he has examined, Plimmer's bodies have been present. In one case of apparently benign but recurrent adenoma of the breast, only a few were found. It was observed that Plimmer's bodies are rare, and not so well defined in sarcoma as in carcinoma. Their demonstration is difficult. In the fresh state they take Sudan III, or they may be fixed by dropping wet smears into Hermann's fluid or by dropping peritoneal coagulum into Hermann's fluid. They are usually intracellular and often several may be detected in a single cell. They are never found in conditions other than tumors in which cellular degeneration is taking place. An effort was now made to identify this microorganism. As it did not appear to be a yeast and could not be cultivated upon media, (64 different varieties having been tried) their attention was attracted by its similarity to the vaccine bodies described by Funk, and he therefore concludes that they are protozoa. They are apparently capable of producing suppurative lesions in human beings, for in one case of carcinoma of the breast a small abscess was found in the skin, the pus cells of

which contained numerous Russell's bodies, and Gaylord believes that they were the direct cause of the suppuration. In conclusion he gives a summary of the animals inoculated with material and cultures from human carcinoma and sarcoma. There were 41 guinea-pigs, 6 rabbits and 2 dogs inoculated in various ways, most of which lived more than 40 days, and 7 guinea-pigs inoculated with parasites from infected animals which lived about 29 days, proving the rapid increase in the virulence of the organism. In cultures made in collodium sacks which were then implanted in the peritoneal cavities of rabbits the virulence was so exalted that they killed by hematogenous infection in 14 days. It does not appear, however that distinct tumors are found in many of these animals, but large numbers of the parasites could readily be detected in all the fluids and tissues. Two guinea-pigs and 2 rabbits inoculated into the jugular vein showed the peculiar nodules in the lung described in the first pig. Two other animals presented rather doubtful lesions. Gaylord promises a second instalment of his paper in which he intends to describe more fully the inoculation experiments and the methods of cultivation. [J. S.]

2.—Gallaudet reports some interesting cases. The first a man of 39, had developed an aneurysm of the carotid artery as a result of an old injury, which it was considered demanded operation because it was increasing rapidly. Two operations were accordingly done. The first was incomplete on account of the obvious tendency to collapse on the part of the patient. In the second the artery was ligated above the sack and an attempt was made to remove it, but the patient died upon the table. The operation was rendered exceedingly difficult on account of dense adhesions, and profuse hemorrhage. In another case, a man with a carcinomatous growth occupying the roof of the mouth, was operated upon after previous ligation of both external carotids by tracheotomy. All the diseased bone was removed with the Rongeur forceps, and the patient made an excellent recovery. The third case was one of cholelithiasis and suppurative cholecystitis. The patient had had no symptoms except jaundice and moderate evening rise of temperature with clay-colored stools. There was neither local pain, tenderness in the epigastrium nor any leucocytosis. At the operation the gall bladder was distended by pus and contained 2 stones, and a 3rd stone was found impacted in the cystic duct at its junction with the hepatic duct. The recovery was uneventful. Two interesting cases of hernia are also mentioned. One in which the bladder ascended through the right inguinal canal, and another in which the cecum was found in a left inguinal hernia. In operating for hernia he sutures the aponeurosis of the external oblique under the cord.

3.—Edsall has carefully estimated the carbohydrates and nitrogen in a case of diabetes insipidus. The method employed was to precipitate with benzoyl chloride. In the presence of sodium hydrate the carbohydrates dropped down as benzoesters. He found that they were not abnormally increased; that they vary slightly with the quantity of urine, and approximately with the total nitrogen, but that they have no distinct relation to the latter. Restriction of the fluids of the diet reduces their quantity. The object of the paper was to discover whether the quantity of carbohydrates could be taken as an evidence of the extent of the diabetes in the absence of a reducing sugar. [J. S.]

4.—Kober believes that milk may be rendered unfit to use by the development of bacteria; by improper feeding of the animals; by being the product of diseased animals; by containing tubercle bacilli; and by acquiring the infectious organisms after leaving the animal. He has tabulated 330 outbreaks of infectious diseases spread by the milk supply, consisting of 195 epidemics of typhoid fever; 9 of scarlet fever, and 36 of diphtheria. Of the epidemics of typhoid fever 148 were due to disease invading the farm or dairy; 16 were due to intentional dilution with infected water. In 7 cases the cows probably waded in sewage-polluted water. In one case the milk pans were washed with cloths used about the patients. Of the 99 epidemics of scarlet fever, the disease existed at the dairy or farm 168. In 6 cases the helpers had lodged in or had visited infected houses; in 2 cases the infection was conveyed by bottles infected at customers' houses. In 17 cases the dairy helpers were suffering from the disease while handling the milk, and in 10 cases they had acted as nurses. The epidemics were also spread by wiping the

milk cans with infected cloths, by storing the milk in the sick room and apparently by disease of the cattle. Diphtheria existed at the dairy or farm 13 times, and in 3 cases the employes were ill while still handling the milk. In 12 cases the cows were diseased. Of these epidemics 243 were reported from England; 14 from Germany; 5 from France; 5 from Austria and 52 by American and 11 by Scandinavian authors.

Kober believes that the laws now on the statute books regarding milk practically deal only with adulteration, and do not control the methods of handling or preparation. [J. S.]

5.—Wood reports a case of hemorrhage from the larynx for which no cause could be ascertained. He collects 6 similar cases from the literature. In his own case the bleeding was temporarily controlled by an application of suprarenal extract. [J. S.]

6.—Harris reports a case of blastomycetic dermatitis involving the gluteal region, that commenced as a small pimple and then spread, forming a roughened area that itched intensely. This was excised and found to consist of hyperplastic epithelial tissue of the skin enclosing military abscesses and containing giant cells. Scattered through the tissue were numerous circular or oval bodies, evidently blastomycetes. Cultures were not made. [J. S.]

7.—Atlee reports 3 cases of subinvolution of the uterus. The first, a woman of 23, after the birth of her first child still had an enlarged, tender uterus with patulous os and profuse leucorrhoea. The 2nd, a woman of 32 had been subjected to a criminal abortion. She had severe leucorrhoea and the uterus was greatly enlarged. The 3rd, a woman of 38, after the birth of a still-born child had leucorrhoea, the uterus was also enlarged and patulous. All these cases were treated by 1 gr. of ergotin three times a day, and magnesla sulphate. They all recovered. [J. S.]

VRATCH.

March 31, 1901. (Vol. XXII, No. 13).

The entire number is devoted to biographical sketches of the late V. A. Manassein.

April 7, 1901. (Vol. XXII, No. 14).

1. Chavkin's Lymph and Other Substances Elaborated in the Human Organism Producing an Immunity Against the Plague. A. F. VIGOURA.
2. Balantidium Coli as the Cause of Chronic Diarrheas. N. S. SOLOVIEFF.
3. Gastrotomy for the Removal of a Glass Tube which was Swallowed and Imbedded in the Stomach. V. V. ROSANOFF.
4. Koumiss-Cure and Some of the Koumiss Settlements of the Government of Oufim. P. V. TSESAREVSKI.

1.—Will be abstracted when concluded.

2.—Solovieff made an exhaustive study of a case of ulcerative colitis caused by balantidium coli, which terminated fatally. An examination of histological preparations showed that, contrary to the general opinion, the balantidium coli are not confined to the mucous membrane of the large intestine. Owing to their independent motility, they penetrate between the intestinal glands, then into the submucosa where they multiply and migrate further through the muscular layer into the subserous. All along their course they produce coagulation necrosis of the tissues. This fact explains the chronic course of the affection as well as the relapses, after the parasites have disappeared from the feces. Several excellent microphotographs illustrate the author's findings. [A. R.]

3.—Rosanoff reports the following case: A peasant, while in a state of intoxication, put into his mouth a few coins which he intended to spend on more liquor. At that time he happened to say something to his wife and at once began to choke. He spit out the coins except one which he believed had entered his throat. He seized a glass tube from the table and tried to push the coin down. In the effort the tube slipped into the stomach. For nearly six months the man went about his usual work without the least discomfort. Finally the tube changed its position in the stomach, and gastric disturbances ensued, followed by emaciation. Gastrotomy was performed and a glass tube 22 cm. long and 3 cm. in diameter removed. The patient made an uneventful recovery. The coin was found under the table. [A. R.]

4.—Will be abstracted when concluded.

EDINBURG MEDICAL JOURNAL.

April, 1901. (Vol. IX. No. 4.)

1. Light and Color Perception. F. W. ELDRIDGE-GREEN.
2. On the Formation of Crystals, Dendrites and Spiral Structures in Relation to Growth and Movement, Especially Rhythmic Movements. J. BELL PETTIGREW.
3. Remarks on Two Cases of Enteric Fever, Complicated with Rigors and Exacerbations of High Temperature. VINCENT DICKINSON.
4. Pernicious Anemia with an Analysis of Eighty-Seven Published Cases and an Inquiry into the After History of Twenty-two Reported Cures. HORACE C. COLMAN.
5. On the Diagnosis of Thoracic and Cardiac Aneurysm by the Röntgen Rays. HUGH WALSHAM.
6. Osteomalacia. W. E. FOTHERGILL.

3.—Dickinson reports 2 cases in which typhoid fever was complicated with rigors and exacerbation of high temperature. One of the patients was a man, aged forty-five years; and the other was a man, aged sixty years. [J. M. S.]

4.—Coleman's paper is based on the study of 87 cases of pernicious anemia and contains a detailed report of 4 cases which he observed himself. [J. M. S.]

5.—Walsham believes that of all the diseases of the chest for which the Roentgen rays may be used for the purpose of diagnosis there is none in which they are of greater value than in the diagnosis of thoracic aneurysm. He feels justified in asserting that it is the duty of the physician to make use of this method of examination in all doubtful cases of chest disease especially if aneurysm be suspected. He gives the notes of 5 illustrative cases together with 9 reproductions of skiagrams. He believes that a transverse position of the heart is an important sign of intrathoracic aneurysm. [J. M. S.]

6.—Fothergill reports the case of a Polish woman, aged 48 years, who had had 9 pregnancies, 8 of which ended in the birth of living children. Toward the end of the sixth pregnancy she began to suffer pain in the hips and legs and discovered that she could not walk easily. The seventh labor was instrumental and was followed by slow improvement, during which she became free from pain, but muscular weakness and difficulty in walking remained. During the eighth pregnancy, which occurred 2½ years later, the pains in the hips and legs returned and were accompanied by pain in the sacral and lumbar portions of the vertebral column and in the arms. After labor, during which she was delivered of a dead child, considerable improvement followed and she was again able to walk without sticks. She became pregnant the ninth time and the usual symptoms returned. It was necessary to deliver this child by Cesarean section, after which improvement again took place until the patient was again free from pain and could walk with out support. With the exception of a large ventral hernia the patient remained fairly well for about 6 years; but during this time noticed an alteration in the shape of her body. Three years ago the pain returned in the back and legs. It became very severe and spread to the arms and chest, she began to suffer from bronchitis and finally became bed-ridden. Under appropriate treatment, which included large quantities of cod-liver oil, improvement again took place so that she was able to walk with slight support. The author believes that osteomalacia is due to a primary affection of the central nervous system, probably beginning in the nerve cells of the anterior horn of the spinal cord. The author believes that in men and in non-pregnant women internal medication should always be patiently tried together with hygienic and dietetic measures. In females, if the disease continues to progress, double oophorectomy may be performed and should be followed by continued medication. In early pregnancy, abortion should be induced and suitable medication be established. In late pregnancy, if a living child cannot be born at term, it is necessary to choose between the induction of premature labor and Cesarean section. During labor if the abdomen is opened, the ovaries should be removed whether the uterus is or not. [J. M. S.]

1.—Will be abstracted when finished.

2.—MacKenna, after a study of 78 cases of syncytioma malignum, finds that the majority of the cases occur between the ages of 25 and 35 years. Hydatid mole preceded the disease in 38 cases; parturition at term in 24 cases; and abortion in 15 cases. There does not seem to be any very precise relationship between multiparity and the development of the tumor. Hemorrhage is usually the earliest and the chief symptom of the disease. Part of it comes from the capillaries of the uterine mucosa but the greater part probably comes from the vessels deeper in the uterine wall whose coats are broken through by the advancing tumor cells. In all probability each profuse hemorrhage is due to the successful penetration of the walls of one of these deeper vessels by the tumor cells. The following points are of value in making a diagnosis: (1) the fact that the patient is usually in the prime of her reproductive epoch; (2) the fact that at some recent date she has been confined, has aborted or has expelled a hydatid mole; (3) the hemorrhagic character of the disease; (4) the rapidity with which metastases develop, particularly along the blood channels. Macroscopically, the mass brought away by the curette resembles the tissue removed in an ordinary case of retained placenta. Microscopically, the tumor contains syncytial cells and cells from the layer of Langerhans. The author believes that the tumor is a malignant degeneration of the cells investing the villi of the chorion and that the involvement of the decidua serotina is secondary. There is great danger attending upon retention of placental remains of fragments of hydatid mole and in all cases it is of great importance to make sure that no remnants of fetal tissue are left in the uterus. In the event of any repeated bleeding following the termination of gestation the uterus should be explored and curetted and the tissue removed and examined microscopically. The uterus and its appendages should be removed as soon as signs of the disease are discovered, unless there is some strong contraindication. The cause of the malignant changes, in the author's opinion, is the presence of some unknown toxin in the blood. [J. M. S.]

4.—Leaf describes an apparatus which he uses in order to produce suction of the tissue involved and the tissue neighboring to malignant tumors to the mammary gland. The apparatus is applied to the breast and worn as long as it gives the patient no inconvenience, a time varying between 6 and 15 hours out of the 24. If ulceration is not already present in the tumor the author does all that he can to encourage it by the constant use of the boracic fomentations which have the additional advantage of softening the fibrous tissue which is present and clearing the channels in which the cells and cancer juice travel. The treatment is recommended in cases of ulcerating scirrhus adherent to the pectoral muscles, in which the axillary glands are much enlarged, matted together and attached to the thoracic wall. It is also recommended in cases in which after one or more operations the growth has recurred in the pectoral muscle, in the lymphatic glands or in both. The author believes that the suction produced by his apparatus draws the cancer juice and the cancer cells and the microorganisms, if there are any, to the surface and prevents them from becoming carried to distant parts in the lymphatic circulation. He reports the case of a woman, 76 years, in whom the shield was worn for nearly 4 months. During this time although the ulcerated surface became slightly more extensive, there was no evidence to show that the glands were becoming affected or that the disease was spreading along the lymphatics. The treatment was finally stopped in order to allow the patient to have her

breast amputated. In another patient, aged 67 years, the shield was worn from 7 to 9 hours out of the 24, and there was a weekly discharge of from 10 to 15 ounces. As a result of the treatment the area of involvement in the breast has undoubtedly increased, but the degree of hardness is decidedly less marked and is sometimes almost soft. The discharge has become more offensive and there has been more sloughing. On the other hand the axillary thickening is undoubtedly less. In a third patient, aged 34 years, the shield was worn from 4 to 8 hours out of the 24. Since the commencement of the treatment the nodules of which there were 3, have become more prominent, but distinctly less adherent to the pectoral muscle. The axillary thickening, however, has not advanced at all. [J. M. S.]

5.—Gibson has noticed an exaggeration of the cremasteric reflex in cases of sciatica. The phenomenon was observed not only in the more serious types of disease, but also in the less grave varieties not accompanied by muscular wasting and changes in electric responses. The reflex may be obtained in the ordinary way, but is more easily produced by firm pressure over the lower and inner portion of Scarpa's triangle. The sensory nerve supply is derived from the internal cutaneous branch of the anterior crural nerve, which is the afferent segment of the reflex arc. The efferent segment is the genito-crural nerve, which has its origin in the first and second lumbar segments. The great sciatic nerve has its origin in the fourth and fifth lumbar and the first, second and third sacral segments. Therefore, there is no direct connection between the great sciatic nerve, on the one hand, and the genito-crural nerve on the other, and this seems to indicate that in sciatica the segments of the cord above those from which the great sciatic nerve takes its origin are in a state of excessive irritability. [J. M. S.]

6.—In operating for strangulated hernia it is very common to meet with circulating grooving of the bowel at one or both ends of the loop engaged in the hernia. When the intestine is liberated and handled the grooves almost invariably recover. They may, however, persist and in this case the symptoms of obstruction continue, instead of being relieved by the operation or they may become the seat of a fibrous stricture. The stenosis that results from persistence of the constriction grooves is an urgent condition. If the belly is opened the damaged loop of bowel will be found in the same condition that it was in at the time of operation. The treatment consists either in immediate resection of the damaged portion of the bowel or in relieving the obstruction by enterotomy. The stenosis that depends upon the formation of a fibrous stricture is of gradual development and the associated symptoms do not make their appearance until an interval of weeks has elapsed since the original strangulation. In such a case when the abdomen is opened the damaged loop of intestine is usually found in the vicinity of the previous wound and is frequently discovered to be fixed in this region by adhesions. After the adhesions are separated the affected loop is found to present a fibrous stricture at one or both ends in the position of the constriction rings observed at the first operation. Above the stricture the intestine is greatly distended and its walls hyperthrophied; while below, its walls are collapsed and the gut is empty. Under these conditions the treatment is directed toward relieving the obstruction and getting rid of the stricture. This may be accomplished by resecting the stricture loop immediately or doing an enterotomy above the proximal stricture and resecting the bowel at a later period after the distention has been gotten rid of. The latter method is Thomson's preference. [J. M. S.]

and Infantile Typhoid, Scarlatina Complicating Typhoid and Vice Versa. J. FINLEY BELL.

4. A Case of Streptococcal Infection Successfully Treated by Antistreptococcus Serum. J. S. FOWLER.

1.—The article by Stengel and White on the blood in infancy and childhood which began in the April number, is finished in the current number. The first changes observed in most cases of disease affecting the blood is a reduction in the hemoglobin and in the number of the erythrocytes, but as a rule the reduction in coloring matter is greater than that of the number of cells, especially in young infants and young children. When erythroblasts are found in the circulating blood after the second or third day of life their presence may usually be assumed to indicate a pathological change. The significance of erythroblasts is, however, much less in infancy and childhood than in the adult since marked anemia occurs so much more readily in early life. Leukocytosis is more frequent in the blood of anemic children than in adults, and the increase may reach enormous proportions in apparently slight pathological conditions. The causes of leukocytosis in children are, in general, the same as those which produce the condition in adults. We may distinguish toxic, inflammatory, posthemorrhagic and cachectic forms. Enlargement of the spleen may or may not accompany the leukocytosis. During an attack of an infectious disease there is often but little change in the number of red corpuscles and the percentage of hemoglobin, while during convalescence a moderate or severe grade of anemia presents itself. The number of leukocytes is increased in some diseases and is unaffected or decreased in others. Among those diseases in which there is no leukocytosis are German measles, early stages of smallpox, mumps, influenza, malaria, typhoid fever, tuberculosis and chickenpox. In an infectious leukocytosis the polymorphonuclear elements are the ones usually involved. In typhoid fever the number of leukocytes is decreased in children as in adults, and there may be at the same time a decrease of the hemoglobin and of the red corpuscles. In pneumonia there is nearly always some degree of leukocytosis which is often excessive. When leukocytosis is absent the prognosis is unfavorable in children as it is in adults. Rotch found that leukocytosis develops from 6 to 12 hours before physical signs are discoverable, and that a leukocytic crisis may antedate the crisis of temperature by 24 hours. A blood lysis is, however, more common. Hereditary syphilis is often accompanied by an anemia which under certain conditions may become very great. This anemia is characterized by decrease of the erythrocytes accompanied by poikilocytes, microcytes, macrocytes, by the presence of polychromatophilia and nucleated erythrocytes. Leukocytosis is present and at times may reach a very high grade with predominance of the lymphocytes. The presence of myelocytes is noted and the hemoglobin is greatly decreased. Slight acute inflammatory processes of the respiratory tract may cause oligochromemia and oligocythemia; chronic processes scarcely ever do. The authors have examined the blood from cases of pneumonia, typhoid fever, whooping cough, chickenpox, tuberculous caries with cold abscess, acute rheumatism, noma, bronchitis, pleural effusion, enteritis, mitral heart disease, rickets, eczema, local epilepsy, convulsions, spastic cerebral palsy and chronic meningitis. [J. M. S.]

2.—After a study of the value of the Widal reaction in infancy and childhood Morse believes that it is safe to conclude that this reaction occurs under the same conditions and with the same limitations in children as in adults. There is some evidence to show that in them reaction appears earlier, is feebler and persists a shorter time than in adults. The serum test, therefore, is of especial value in 2 ways in the diagnosis of typhoid in children; first in ruling out many cases of gastrointestinal disorders which might otherwise be mistaken for typhoid, and second, in making a positive diagnosis possible in many mild cases which might otherwise pass unrecognized. In early infancy

a positive Widal reaction is of somewhat less diagnostic value than in older children and adults. If the mother has had typhoid, and especially if she is nursing the infant, it should be looked on with some suspicion, unless associated with other characteristic signs of typhoid. Examination of the mother's blood and milk and the cessation of breast feeding will then assist the estimation of the true value of the reaction in the infant. The Widal test also promises to be of great value in the determination of the frequency, symptomatology and pathology of infantile typhoid. The employment of this test in large series of cases, not only of supposed typhoid, but also of other gastrointestinal disorders cannot fail to add much to our knowledge of these vexed questions even if it does not positively settle them. [J. M. S.]

3.—Hall records his experiences in a local epidemic of typhoid fever. One of the cases occurred in a pregnant woman and resulted in a premature labor at 8 months. The baby also presented typhoid fever. One of the patients also presented scarlet fever as a complication of typhoid fever, and another patient was taken ill with scarlet fever and subsequently developed typhoid. [J. M. S.]

4.—Fowler reports the case of a boy, aged 19 months, who was suffering from vomiting and diarrhea. The patient also presented a mucopurulent nasal discharge, dacryocystitis, stomatitis and a patch of bronchopneumonia. There were 2 distinct attacks of bronchopneumonia. Under the use of antistreptococcus serum the patient recovered. During convalescence he developed measles from which he also recovered. The stomatitis was due to the presence of streptococci and the general streptococcus infection started from that lesion. [J. M. S.]

NEUROLOGISCHES CENTRALBLATT.

1. The Pathogenesis and Clinical Manifestations of Cramps in the Calf Muscles. P. NÄCKE.
2. A Case of Superficial Softening in the Area of Distribution of the Sylvian Artery. G. BIKELES.
3. Contribution to the Histology of the Changes Produced in the Spinal Cord as the Result of Compression by Vertebral Tumors. M. BIELSCHOWSKY.

1.—Näcke deplors the ignorance that exists concerning such a common and important symptom as **cramp in the calf muscles**. Various theories have, however, been suggested, among these are hypotonia of the antagonistic muscles, and fatigue of the calf muscles themselves, but as the symptom often occurs in the very beginning of exercise, and is no more likely to take place during the night after severe exercise, then after a day of rest, Näcke believes that it is probably the result of violent shortening of the muscles, or some defect in movement. The normal man usually sleeps upon the side with the joint slightly flexed, that is, the muscles are probably in a state of equilibrium. In this position, however, it is possible that excessive contraction may from time to time take place. Pressure upon the arteries does not seem to be of any significance, because women who habitually wear garters are not more subject to this manifestation than are men. Among certain predisposing causes are infectious diseases, certain forms of poisoning, and other states that bring about an abnormal condition of the blood. Why, however, the calf muscles should be particularly involved is not clear. Nervous influences are doubtful. Some authors, as for example Féré, believe that they are of considerable importance, but Näcke has failed to observe the symptoms more frequently in neurasthenics and epileptics than in others. Regarding the symptomatology of this disease Näcke speaks of localized cramps in the calf muscles occupying only one side, or cramps first in both legs or in one immediately after the other, or repeated attacks. In some cases the cramp is almost clonic in character, and the pain may persist some time after the attack. In one instance Näcke was able to observe it in himself three days later. He calls attention to a peculiar condition that he names "abortive cramp," that is to say, a slight contraction of the muscles that can be overcome by effort. This is

particularly interesting in connection with the theory of musculo-cutaneous origin. The major cramps of course awaken the subject at once, but it is possible that these abortive cramps might produce characteristic dreams. However, their duration is probably too brief. In conclusion he speaks of the fact that these cramps are invariably peripheral in character, and states that Dexler has informed him that they do not occur in the lower animals. [J. S.]

2.—The patient, a man of 29, had always been in bad health, with weak cardiac action. He developed edema of the left lower extremity, and 2 days later had paralysis of the left upper extremity and left side of the face, and paresis of the left lower extremity. The superior branch of the facial nerve, and the motor portion of the trigeminus were not involved. The tendon reflexes were exaggerated on the left side, and the cutaneous reflexes on the right side. Touch and pain sense were diminished on the entire left side, and temperature sense on the left side with the exception of the face. An examination of the heart led to the diagnosis of defect of the septum of the heart, stenosis of the pulmonary artery, tuberculosis of the lungs, thrombosis of the veins of the left leg, and embolism of the Sylvian artery. The patient died in the course of 18 days. At the autopsy there was found an area of softening composed of numerous closely aggregated focal lesions occupying the entire area of distribution of the Sylvian artery. There was also some hemorrhage into the pia arachnoid. Sections were made and stained by the Marchi method, and showed degeneration involving exclusively the pyramidal tract in the medulla and of the few fibres in the right fillet in the pons, probably corresponding to the motor fibres described by Hoche in this region, an area of degeneration in the posterior limb of the internal capsule corresponding to that described for hemiplegia, but slightly more extensive. In the right crus degeneration was found in the medial portion, but none in the external third. The case is interesting because of the extensive degeneration, the left upper branch of the facial nerve remaining intact. It is possible that the sensory disturbances which involved the left side nearly uniformly, were due to functional, and not organic lesions. [J. S.]

3. In concluding his paper Bikeles calls attention to the fact that of the 3 cases reported by him in which the spinal cord was subjected to external pressure, 2 showed no trace of inflammation. Both of these, however, were characterized by the wide-meshed proliferation of the glia which is produced by the swelling of the myelin sheaths. He is unable to convince himself that the compound granular cells are derived from the leukocytes, but he is inclined to regard them as neuroglia cells, or connective tissue cells of the vessel walls. In the third case that had probably been subjected to pressure longer than the others there was distinct proliferation of the neuroglia tissue. The paper is still unfinished. [J. S.]

April 16, 1901.

1. The Disturbance of Deep Sensation. A. PICK.
2. A Stain for the Axis Cylinder. Preliminary Communication. L. KAPLAN.
3. The Histology of the Changes Produced by Compression of the Spinal Cord in Diseases of the Spinal Column. M. BIELSCHOWSKY.

1.—Pick has observed a case of a man, 43 years of age, suffering from general paresis. Whilst under observation the patient had an apoplectic attack in which the head was turned to the right, and there was paresis of the left facial nerve. There was complete loss of pain sense in the left arm, and almost complete loss in the left leg. There was also flaccid paralysis of the limbs on the left side. The next day the patient had improved very much and upon examination it was found that he had a left-sided hemianopsia, and there was extreme ataxia when the patient attempted to grasp any object. This ataxia gradually disappeared, and the patient returned to his former condition. At his death, some time later, the typical changes of general paresis were discovered. As it might be supposed that the disturbance of deep sensation was the result of the hemianopsia, Pick reports 2 additional cases in which the same symptoms did not exist. He also calls attention to the interesting experiments upon animals made by various authors in which, after destruction of the parietal lobe, loss of the position of the limbs could be determined. [J.S.]

2.—Tissues are hardened in Müller's fluid for 3 months

or more, then in alcohol for a day, and imbedded in celloidin or paraffine, and sectioned. They are then stained in a freshly prepared 10% aqueous solution of anthracene elcengalic ink for 3 days at 55°. Then washed in water, differentiated in potassium permanganate and nascent sulphuric acid (as in Pal's method); then washed in water, dehydrated, and mounted in xylol colophonium. A peculiar substance of the axis cylinder that commences a short distance from the cell and terminates a short distance before the end arborization is stained. [J. S.]

3.—Bielschowsky concludes his article. In the 2nd case the cross section at point of compression presents the typical picture of moderate softening. The pia was not involved, and there the question necessarily presented itself as to whether there was not some inflammatory action, or at least a toxemia, the result of the tumor. As in this case, however, the tumor was merely an exostosis, the latter supposition is excluded. He believes that the appearance is due merely to the disintegration of the spinal cord brought about by pressure. He also calls attention to several interesting features, first, a bundle of fibres that were found in the anterior commissure and in the adventitia of the central bloodvessels at the point of compression. These, he believes, are fibres pursuing an atypical course, although he discusses Flekier's supposition that regenerating fibres may be found in the spinal cord. In the 3rd case he calls attention to the cavity formation above the point of the compression and suggests that it is due to the obliteration of the central canal. Mendel has suggested that this is due to the interference with the flow of cerebrospinal fluid as a result of the proliferation of the neuroglia tissue, that is, a sort of gliomatosis. This, Bielschowsky regards as perhaps too sweeping, and he believes that in his own case there existed, as a result of the carcinoma of the vertebrae, a hydromyelia of the cord, following which the compression occurred. He believes that the clefts found in the anterior cornua are to be regarded as secondary to the rarefaction of the tissue. [J. S.]

10. A Further Reply Concerning the Influence of Artificial Sweating upon the Secretion of Gastric Juice (in reply to Dr. Paul Edel). ALEXANDER SIMON.

1.—The method adopted by Rubinstein consisted in excising a portion of the ribs of rabbits, and carefully counting all the different varieties of cells in sections of the marrow, and at the same time counting carefully the white cells in dried preparations of the blood. Immediately thereafter the rabbit was injected with a leukocytotic; he used chiefly streptococcus cultures, turpentine, deutoalbumose and extract of spleen. The results from these substances were about equally good. The conclusions which he reaches are that leukocytosis (purely in the sense of an increase of other cells than the lymphocytes) is a function of the bone marrow only. After injection of the leukocytotic there is an increase of polymorphonuclear cells in the blood current, and in the bone marrow one finds an increased production of large homogeneous mononuclear cells which subsequently show granulations and are therefore the direct predecessors of myelocytes; these subsequently by nuclear changes become polymorphonuclear leukocytes. If the leukocytosis is prolonged, there is such an increase of myelocytes that these cells amount to much more than half the total number of cells in the bone marrow. The granules found in the large homogeneous mononuclear

cells may be observed in the process of formation, and in the early cells and in the early stages are basophilic. There was no evidence of any formation of granulated cells in the blood current or in the spleen or lymph. The large homogeneous mononuclear cells mentioned are developed from small lymphoid elements which are found in every bone marrow, but which are formed there, and have no relation to the lymphocytes of the lymph system. These facts are sufficient to demonstrate the incorrectness of the Uskoff teaching that the white blood cells are all derived from true lymphocytes. The eosinophilic leukocytes are derived, as are the pseudoeosinophiles and the neutrophiles, from lymphoid cells of the bone marrow. Intermediate stages between neutrophiles and eosinophiles cannot be observed in the blood or in the bone marrow. The process of development of the leukocytes in the bone marrow is through the following stages: There is first a small lymphoid cell with a nucleus showing distinct structure and with a small, distinctly basophilic, ungranulated protoplasm; second, a larger lymphoid cell with a large nucleus with distinct structure and a broad ungranulated protoplasm; third, a large lymphoid cell with a nucleus that does not show distinct structure but has a broad ungranulated protoplasm; fourth, a mononuclear ungranulated, large lymphoid cell, with a round nucleus, that takes stains weakly, with clear ungranulated protoplasm; fifth, the myelocyte; sixth, the polymorphonuclear leukocyte, the granules in the rabbit being pseudoeosinophilic; seventh, eosinophilic cells going through the same process with the single difference that the granules are from the beginning larger, and soon show the eosinophile stain instead of the neutrophile. [D. L. E.]

2.—The article is an extended description of the apparatus devised by the author, of the methods of its use, and of the results derived from its use. It has no special practical value, and is not subject to abstracting. [D. L. E.]

3.—The case described was observed in a woman of 31 who presented the usual characteristic appearances of acromegaly. There is a very careful series of measurements of all the regions of the patient's body and extremities, and these are compared with those of the normal person at the same age. A radiograph shows the changes in the hand and arm, and the contraction of the field of vision for white and colors is exhibited in illustrations. It is believed that this case could be clinically considered to be due to enlargement of the pituitary gland, since there was imperfect vision in both eyes, contraction of the field of vision, and more particularly, temporal hemianopsia. The disturbance of vision had been present for years and was constant, hence its cause was also constant and therefore probably organic. This cause was probably some disturbance of the chiasm in the posterior part, and this would give reasonable suspicion of enlargement of the hypophysis. It is commonly stated that in acromegaly the cardiac dulness, particularly over the left ventricle, is enlarged, this being attributed to the thickening of the arteries. In this case the heart was not hypertrophied, and there was no accentuation of either second sound. The patient had, however, attacks of heart weakness. It was interesting to note that both the heart weakness and the disturbance of vision had begun practically coincidentally, about six years before the patient came under observation, and the heart weakness was apparently functional; it is suggested that the functional disturbance of the heart was produced by altered function of the pituitary body. There has been no previous discussion of the functional changes of the heart in acromegaly, and Trachtenberg considers that this question should be more carefully studied. As to the relation between the pituitary body and acromegaly, he states that our knowledge is not yet definite, but he believes that we must recognize that there is a distinct relation between changes in the hypophysis and this disease; it is certainly true that the two have been observed frequently to exist together. But what the disturbance is one cannot say off hand, as in some cases there has been atrophy of the hypophysis and in other cases hypertrophy. There is some obscure relation between the hypophysis and the thyroid, and there is a rather striking analogy between the results of different forms of alterations of the thyroid and those of different varieties of changes in the hypophysis. [D. L. E.]

4.—Hampeln contributes a very interesting discussion of aneurysm and mediastinal tumors and the differential diagnosis between these two conditions, based upon a series of about 150 cases of aneurysm, about 200 cases of stenosis of the esophagus, and a large number of other

cases of mediastinal tumor. The conclusions which he has reached from his clinical work and the observation of a large series of autopsies, are that the most important signs which give evidence of mediastinal disease are stenoses and pressure paralyses, the latter chiefly involving the recurrent nerve. Tracheal stenosis is the most important of the various forms of stenosis, and if it is present the probability of the presence of aneurysm is very great. In 20 cases of tracheal stenosis aneurysm was present 18 times, tumor but twice. The stenoses of the bronchi are of much less importance because they are present in about the same percentage of cases of neoplasm as of aneurysm. Esophageal stenosis speaks very strongly for the presence of neoplasm. This more especially refers to permanent disturbance of deglutition; a subjective feeling of difficulty in swallowing may be met with in aneurysm, but also in general dilatation of the aorta. The latter feeling was noted in 14 of 95 cases; but these feelings are only temporary, and are very different from the characteristic symptoms of actual stenosis of the esophagus. Distinct permanent stenosis of the esophagus is in his experience a great rarity in aneurysm; he saw it but once in 140 cases. In 4 cases the postmortem showed compression, and in 3 instances perforation, but only slight difficulty in swallowing or none at all was ever complained of. The reason for this is that the aorta can exert only a one-sided pressure upon the esophagus. The course of the esophagus becomes somewhat distorted because of this, but as a rule nothing else results. He has reached the conclusion, therefore, that permanent signs of stenosis of the esophagus constitutes almost secure evidence of mediastinal disease, and excludes aortic aneurysm. Only rare exceptions to this rule will be found. Paralysis of the recurrent on the left side was noted in 30 instances, 25 of these were aneurysm, 5 neoplasm. It is, however, to be observed that the percentage of paralysis of the recurrent in aneurysm is about the same as that in neoplasm. If the paralysis occurs in a person of middle age, particularly if there is a syphilitic history, it speaks decidedly in favor of aneurysm, but if it occurs in an older person, and especially when there is cachexia, it indicates carcinoma. Hemorrhage from the lungs is an extremely important sign in carcinoma, as it indicates severe pressure, and is usually premonitory of rupture. A similar sign is, however, frequently observed in carcinoma of the lungs and bronchi. [D. L. E.]

5.—The case reported by Holdmöser occurred in a man of 48 who was observed through two periods, one of them in the early part of the summer of 1900, the other in the fall of 1900, death occurring at the end of the latter period. His chief subjective symptoms were cough, and dyspnea, which at first improved but afterward grew worse, and death occurred from cardiac insufficiency. Physical examination of the man showed as the most pronounced signs about the heart a strong pulsation on the left of the sternum most marked in the second intercostal space, a marked thrill at this region, and a loud systolic murmur heard most markedly at this area, but also on the right. In the beginning of the disease there was also a diastolic murmur at this point, and there was also a systolic murmur of a different character heard over the left ventricle. The left ventricle was decidedly hypertrophied, the right less so. The second pulmonary sound was marked by accentuated, and the pulse was decidedly quick. There was dulness over the sternum and over the area of pulsation. The affection was evidently an aneurysm, the main question being whether it was an aneurysm of the root of the ascending aorta or of the pulmonary artery. Holdmöser discusses these various possibilities, stating that the conclusion reached was that there was an aneurysm of the lower part of the ascending aorta extending toward the left side, and there was also thought to be a mitral insufficiency. He discusses the possibility of a diagnosis of aneurysm of the pulmonary artery, the admissible conclusion being that this diagnosis is often impossible and at least extremely uncertain. The autopsy showed aneurysm of the ascending aorta extending toward the left, compressing the pulmonary artery and showing a perforation about the diameter of a pea with thickened edges; it had evidently been present for a long time before death. The left ventricle was much hypertrophied and dilated; the right ventricle was dilated and but slightly hypertrophied. The right pulmonary valve was completely adherent to the wall of the pulmonary artery. There follows a theoretical discussion of the origin of the murmurs, in which no definite conclusion is reached excepting that

the diastolic murmur heard over the pulmonary region was probably not due to insufficiency of the pulmonary valves, but was produced in the aneurysm itself. This diagnosis was made during life, and although the autopsy appearances did not seem to confirm it, Holdmöser thinks that the adhesion of the pulmonary valve probably did not allow of regurgitation, but that the aneurysm pressed this valve over far enough to prevent regurgitation. The study of other cases of rupture of an aneurysm into the pulmonary artery shows that the cases are to some extent suggestive as to diagnosis. A loud systolic murmur was heard in all cases on the left in the second intercostal space; dulness and thrill were found in the same region. The murmur was transmitted to the back, chiefly on the left. A diastolic murmur was heard in a number of cases, and was in most of these cases shown to be due to coincident insufficiency of the pulmonary valves. There was a decidedly varying condition as regards overfilling of the veins. It was notable that in several cases in spite of dyspnea the patient preferred to lie down. Holdmöser has found six other cases in which there was evidently a healed perforation like this. The clinical signs of the perforation itself are not at all distinctive; they may be quite as well due to compression. The perforation is probably of marked importance in itself only when it is very large, or when the right heart has already become insufficient. The radiogram showed an abnormal shadow toward the right, and an unduly broad shadow toward the left. Such a shadow might be due to pulmonary aneurysm or to aneurysm of the aorta extending toward the left, but when such a shadow is observed it is wise to think of the possibility of either aneurysm of the pulmonary artery or compression by an aortic aneurysm. [D. L. E.]

7.—Adamkiewicz gives a somewhat obscure physiological-psychological discussion of the function of the ganglion cells of the cortex. [D. L. E.]

8.—The changes found in the blood by Stejskal are summarized by him as follows. In the whole blood the albumin was decreased, the dry residue was lessened, the water and salts were increased, the fat and cholesterol were lessened, the lecithin unchanged, the calcium and potassium salts were increased, the chlorides and iron decreased, the sodium practically unchanged. The serum showed chiefly a decrease of the albumin and a coincident decrease of the dry residue, and increase of the ash and water. All the components of the ether extract had decreased. The potassium were increased, the chlorides decreased. The erythrocytes were poorer in albumin, lecithin and cholesterol, and richer in water and salts. This was evidently due to imbibition of fluid rich in salts, particularly in chlorides, that is, imbibition of plasma. The weight of the erythrocytes was increased, the amount of plasma decreased, but the plasma was poorer in albumin and richer in water and salts. The question as to the origin of these changes could not be definitely settled; it might be due to lack of nutrition, to the disease itself, or to the fever. The fact that the salts had increased spoke against the possibility of inanition as the cause, and further plenty of nourishment had been taken; the disease itself may have been the cause, but there is not sufficient knowledge of the effects of disease to state this. The effects of fever *per se* have been studied to some extent, however, and from a comparison of results found in this case Stejskal decides that very probably the conditions were due to the fever itself. [D. L. E.]

1.—Perez has collected the various clinical observations upon the different localizations of the influenza bacillus.

especially those needing surgical treatment, and the varied complications and sequelae of influenza; seeking to explain them by experiments. The difficulty of isolating the influenza bacillus, the occurrence of other micro-organisms with it, and the similarity between it and the pseudo-influenza bacillus, made his work extremely difficult. As long as these micro-organisms are found with the influenza bacillus, it can not be proved that the processes occurring, which necessitate surgical interference, are the result of the influenza bacillus alone. No doubt longer exists that influenza is due to the Pfeiffer bacillus. Perez describes the influenza bacillus in detail, with a review of the literature of its morphology and pathogenicity; its staining properties, and the effects caused by it when inoculated into animals, from his own experiments. Among the changes produced in the skin by influenza are alopecia, erythema, eczema, purpura, and other eruptions with desquamation. It causes inflammation in the muscles, fasciae, and connective tissue, with infiltration of the leucocytes and abscess formation. It causes bronchopneumonia, abscess of the lung, and pleurisy which is generally purulent. In all of the inflammations due to the influenza bacillus, the tendency of both red and white blood corpuscles to escape through the blood-vessel walls seems markedly increased. Perez expects to continue his experiments, and will publish the results of influenza upon the rest of the body later. [M. O.]

2.—Merkens reports some of his own cases and some from the literature, to show the occurrence of intracranial complications, meningitis, sinus phlebitis, brain abscess, and encephalitis, with purulent otitis media. A woman with left otitis media had the base of the skull fractured, but recovered. Three months later severe pachymeningitis occurred, with death on the third day. Autopsy showed more lesions on the left of the brain than on the right. Merkens believes the meningitis to have been due to purulent otitis media. The injury undoubtedly had an unfavorable effect upon the middle ear disease. Two other cases of suppurative otitis media following fracture of the base of the skull are mentioned. The differential diagnosis between meningitis and brain abscess is difficult; high fever, rapid pulse, convulsions, with rapid change of symptoms are found with meningitis; normal temperature, slow pulse, increasing paralysis, and slow course, with abscess. When the abscess is on the left side, typical speech disturbance occurs. Sensory troubles are due to encephalitis around the abscess, and to increased intracranial pressure. Merkens reports two other cases which died after operation, one of meningitis following purulent otitis media, the other of brain abscess. Both had been correctly diagnosed. He also reports a case of sinus phlebitis following otitis media, and a case of extradural suppuration, both of which recovered after operation. He quotes a number of cases of toxic encephalitis. As serous meningitis and encephalitis are caused by the same toxins, they may exist together, and can easily recover without operation. If bacteria are present, suppuration will occur, and recovery will be doubtful. When the diagnosis of an abscess of any part of the brain, or of sinus phlebitis is made, operation should be immediate, to save the patient's life. Care must be taken, however, especially in children, not to operate unless positive that suppuration has occurred, for the symptoms with otitis media will often puzzle an expert clinician. [M. O.]

3.—Anuria is rarely seen. Koenig reports the case of a man of 51, given to inordinate beer drinking, who passed no urine for 4 days. His bladder was found empty. He felt perfectly well, and continued drinking. While driving to Göttingen for operation, he stopped and ate a good meal. Only on the ninth day did vomiting appear, and coma came on, with death following, in spite of operation. Koenig says that no symptoms are noticed for 3 days at least. He reports the interesting case of a phthisical girl of 14, whose right kidney was severely affected. Suddenly anuria occurred. Operation was performed, the right kidney opened along its convexity, and a fistula established. Urine flowed through the fistula for a week, then it appeared in the bladder. The fistula healed in a few weeks. Two other cases are reported, of anuria due to stone in the left ureter, one cured by operation, the other spontaneously, by the passage of the stone. [M. O.]

4.—Prophylactically Rose removes the appendix whenever it shows signs of inflammation or thickening, while performing adjacent abdominal operations. Medical treatment of appendicitis he considers useless. The main symp-

tom is constipation, which may even be the cause of appendicitis. **Opium should never be given.** Before operation, the intestines should be disinfected as far as possible. Operation should be performed in the first half of the first week generally, rarely in the first part of the second week. The pulse will show the immediate necessity for operation. 5 operations can be done, simple incision of the appendix, which is rare; amputation of the appendix; extirpation of the appendix; amputation of the cecum; and exairesis of the appendix. After reporting cases to illustrate these operations, making a total of 68 cases reported, Rose concludes, saying that the more he operates for appendicitis, the more he leaves in drainage, and omits stitches in the abdominal wall. **The longer the abdomen is kept open, the more successful is the result.** [M. O.]

5.—Cysts of the pancreas are very rare, and are hardly ever diagnosed. Von Mikulicz, out of his immense operative material, has found cysts of the pancreas only 5 times. Professor Hahn, in 10 years, has seen 4 cases which Seefisch reports in detail. Koerte has divided cysts of the pancreas into three kinds, the traumatic, the inflammatory, and the tumor-like, which increase in size gradually and only show symptoms late. The inflammatory are the most common. One of Seefisch's cases is traumatic, as it occurred a month after the patient had been run over. One case is inflammatory, following parturition, and the two others belong to the tumor-like variety, growing gradually larger without known cause. From these cases Seefisch has collected the following common symptoms as of value in making the diagnosis of cysts of the pancreas: (1) gastric symptoms, pain, tenderness, vomiting, signs of dilatation, etc.; (2) emaciation; (3) their development in the epigastrium, generally somewhat to the left side; (4) their situation near the posterior abdominal wall, upon the aorta, so that its pulsation is seen and felt; (5) their immobility; (6) the stomach (dilated) and the transverse colon are found lying upon the cysts. **Pancreatic symptoms were absent in all four cases, one of which died.** The general method of treatment is that devised by Gussenbauer, marsupialization of the cyst, with drainage through the abdominal wall, to which the opened cyst is sutured. In a few cases the cysts have been extirpated. This would be the ideal treatment, yet it is too dangerous in most cases. [M. O.]

6.—Soerensen reports three cases operated for cicatricial stenosis of the ileum, due to tuberculous ulcers, which he has seen during the past year. Tuberculous ulcers of the intestines are very common, about 85% appearing in the ileocecal region. But cicatricial strictures have rarely come to operation. The first patient had had phthisis for four years before operation. A stricture was found in the ileum, with an opening about 1 cm. wide. Entero-anastomosis was quickly done, as the patient was very weak. In the second case, tuberculous for three years already, several strictures were found in the ileum, the smallest only ½ cm. wide. The ileum was sutured into the transverse colon. The third case was a soldier who had been ill a year, in whose ileum several strictures, none under 1½ cm. were found. Here the ileum was sutured into the ascending colon. No symptoms of acute tuberculous enteritis are found in these cases, the patient showing no intestinal symptoms until stenosis occurs. But there are great emaciation, loss of weight, fever, etc. Then suddenly come the signs of intestinal obstruction. Above the stricture, hypertrophy of the muscular wall of the intestine occurs. In the great majority of cases phthisis already exists. Yet a tuberculous stricture may appear in an individual otherwise perfectly well. Before the symptoms of intestinal obstruction occur, diet will be needed; purgatives are dangerous. When strangulation occurs, operation should be performed at once. Entero-anastomosis and resection of the bowel are the operations to be performed. [M. O.]

7.—Franke reports a case of retrobulbar tumor in a man of 63. By Kroenlein's operation it was impossible to reach the tumor, but after enlarging his incision by scraping away the periosteum of the roof of the orbit, he came suddenly upon the tumor, which could even then only be removed in bits. The bony flaps were replaced, and the wound closed. It healed by first intention, but the result did not benefit the patient much. The tumor was a sarcoma. This led him to attempt an operation upon the cadaver, going through the bone at the level of the eyebrow, thus opening the orbit. This was easily accomplished. Franke advises this new modification of Kroen-

lin's method, as it injures neither muscles or nerves, and permits opening the retrobulbar space widely. [M. O.]

8.—Subbotin reports his second operated case of hemorrhagic cyst of the pancreas. Both of his cases were diagnosed before operation. This one occurred in a girl of 27, in whose left hypochondrium a tumor had grown for two years, following an injury. Laparotomy was performed, the cyst opened and drained through the abdominal wall, to which its edges were sutured. She died of septic peritonitis. Examination showed the tumor to be a chronic, sclerotic, hemorrhagic cyst of the pancreas. The pancreatic duct was not permeable, and other cysts existed near the head of the pancreas. The large cyst had probably been produced by dilated pancreatic ducts, being further enlarged by frequent hemorrhage. [M. O.]

9.—After a series of experiments with wax-covered silk thread, both with bacteria and disinfectants, Saltykoff concludes that it cannot be employed for sutures, for bacteria will penetrate it while disinfectants will not. [M. O.]

ZEITSCHRIFT FUER HEILKUNDE.

1901. Volume IV No. 2.

- 1.—The Lengthening of the Fallopian Tubes with Ovarian and Parovarian Cysts. HARRY LEPMAN.
2. Malignant Myoma of the Uterus. ANTON MASTNY.
3. The Relation between Toxin and Antitoxin. RICHARD KRETZ.

4. The Anatomical Conditions Found in Death from Strangulation and Hanging.—FRITZ REUTER.

1.—From a full review of the literature, Lepman shows that the Fallopian tubes are generally lengthened by the growth of ovarian and parovarian cysts. The tubes rarely become thinner, generally growing thicker, broader, and longer. A table of 14 cases is given, in each of which measurements were made post mortem. From these it appears that the Fallopian tubes in women, except during pregnancy or the puerperium, measure from 9 to 9½ cm. in length, not including the uterine part of the tube, which is from 0.7 to 1.0 cm. long. The isthmian end has a diameter of from 2¼ to 4½ mm.; the ampulla, from 3¾ to 5½ mm. The lumen increases proportionately with the distance from the uterus. Having borne children makes no difference in these measurements. The only differences found in multiparae are that the blood vessel walls are somewhat thicker and the connective tissues more abundant than in virgins. During pregnancy the tubes are pushed out of the way, showing the effect of compression only. Then follows a detailed list of pathological cases in which the Fallopian tubes were lengthened. The tubes have been found five or six times their original length, the ampulla being tortuous. In 7 out of 11 cases examined microscopically, the cause was a parovarian cyst. The increased thickness of the tube is due to hypertrophy of its muscular wall, with some hyperplasia of the connective tissue. The cause of these changes is not only mechanical, from the tumor, but is most probably due to the increased blood supply in the neighborhood of the growing cyst. Thus Lepman believes that the Fallopian tubes take part in the common growth about the tumor, that continued mild, mechanical irritation will cause considerable hypertrophy of the muscle; but that, should truly strong reaction occur, atrophy will follow. Thus atrophy of the tubes is found with very rapidly growing cysts. [M. O.]

2.—While myomata are generally benign tumors, cases have occurred with recurrence and metastases. It is possible for a co-existing carcinoma or sarcoma to have grown into a myoma; or a metastatic growth from either carcinoma or sarcoma to have grown into a myoma; or a metastatic growth from either carcinoma or sarcoma may appear in a myoma; or a mixed tumor may be formed by the simultaneous development of a myoma and a sarcoma or carcinoma. But beside these pseudo-malignant myomata of the uterus, a true malignant myoma may be found. This Williams has called myoma sarcomatodes. Only four such cases have been published. Mastny reports the fifth case of malignant myoma, in a woman aged 45. A diagnosis of myoma of the uterus with malignant degeneration had been made before death. The autopsy revealed an elliptical tumor of the uterus which filled the entire hypogastric region. Small nodular masses were seen upon the flat surface of the tumor. Metastases existed in the broad ligament, lungs, pancreas, bronchial and retro-

peritoneal glands. Microscopic examination showed a muscular tumor of the uterus. Even the sarcomatoid cells show distinctly their derivation from muscle cells. The major part of the tumor was composed of these atypical muscle cells. Mastny showed, by staining them, that the gradual growth and the changes occurring in the muscle cells, with the disappearance of the connective tissue, might be seen. [M. O.]

3.—Kretz, after describing Ehrlich's "side-chain" theory to explain the immunity produced by anti-toxin, shows that this idea cannot be correct, for the antitoxin formation is irrespective of the effect of antitoxin in the animal body. This is also shown by the paradox reaction. Nor does Kretz believe that Wassermann's conclusion that one part of brain substance is identical with one of antitoxin is correct, though it does show the chemical affinity between the toxin and the organ affected. But one function of the toxin has remained hidden, which may be defined as the antitoxin-producing component of the toxin-effect. While Kretz considers pure neutralization of the toxin by the antitoxin, with Ehrlich's theory, incorrect, nevertheless he believes that the "side-chain" idea has helped to explain much. After visiting Ehrlich, Kretz adds that, in spite of recent experiments, Ehrlich's hypothesis does not explain the paradox reaction. Nor will the relation between toxin and antitoxin be understood until further investigations have gone deeper into the subject. [M. O.]

4.—Reuter has examined the bodies of 22 cases of strangulation, 7 of them suicides. Six others were adults, 9 infants. He describes the anatomic conditions found, believing that cyanosis of the face, with or without ecchymoses, and hemorrhage of the conjunctiva and eye-lids are noted in every case externally; internally are seen congestion of the brain and meninges, hemorrhage into the soft parts of the neck, near the line of strangulation, or at some distance above it, and marked injection of the mucous membrane of the upper air passages. In infants, while the external conditions are found the same, only congestion of the brain and its coverings is seen internally. The mechanism of death by strangulation or by hanging is the same, yet the lesions found are different. Reuter has looked over the statistics of 300 cases of autopsy after hanging. He states that there are, as a rule, no cyanosis of the face, no marked congestion of the brain or meninges, and no hemorrhage into the muscles of the neck; that injuries to the larynx are frequent; and that rupture of the intima of the carotids is frequently found. Reuter concludes, after quoting a few cases, that the differential diagnosis of death from strangulation or hanging, should not be difficult when the anatomic conditions found have been thoroughly examined. [M. O.]

CENTRALBLATT FUER CHIRURGIE.

May 11, 1901. (28 Jahrgang, No. 19.)

1. Intermittent Ether Narcosis. KRONACHER.
2. An Apparatus for the Administration of Schleich's Inhalation Anesthesia. LUDWIG MOSZKOWICZ.

1.—In spite of the various methods of local anesthesia general anesthesia has not been superseded, nor has the new spinal anesthesia yet fulfilled expectations. For minor operations chloroform in small quantity is all that will be needed; and it may be given in women and children without harm, little by little, for some time. But much better, according to Kronacher, is intermittent ether narcosis. He gives the ether a few drops at a time, removing the inhaler between a series of inhalations, letting the patient take five to ten long breaths of air, after which the inhaler is replaced. This is continued, thus alternating air and ether, until the excitement stage is reached. Then the ether is pushed for a few inhalations, before it is stopped. By this time, about ten minutes, the patient is anesthetized, and more ether is only given should he begin to come to. Then the same process is gone through again. Thus very little ether is given, and there is no danger. Kronacher has proved that the patient does not feel any pain between etherizations, nor has he any recollection after the operation, of having awakened or cried out during the operation. After effects by this method are gen-

erally absent. Kronacher has used this intermittent ether method for three years with great success. [M. O.]

2.—Moszkowicz describes an **apparatus** consisting of a bottle with two rubber tubes from its stopper, at the end of one of which is a cannula. The Schleich cocaine solution is poured into the bottle till it is half full, and air is pumped in through one tube; closing the stop-cock upon that side, and opening that connected with the cannula-tube, the solution is thus easily injected. As this apparatus makes the procedure much more rapid, Moszkowicz hopes that Schleich's infiltration anesthesia will be commonly employed. [M. O.]

May 18, 1901. (28 Jahrgang, No. 20.)

1. The Use of Magnesium for an Absorbable Anastomosis Button and Other Surgical and Technical Purposes. ERWIN PAYR.

1.—Last year Payr reported the idea of employing an absorbable metal for suturing blood vessels and nerves, and suggested using magnesium in intestinal anastomosis. This Chlumsky has already carried out. Payr has used magnesium plates in a plastic operation on an ankylosed joint to prevent the separated parts of the joint from uniting again. He expects to publish his experiments soon. He has used it in suturing nerves, in injuries of the parenchymatous organs to stop hemorrhage, and in irreducible fractures and pseudarthroses. Payr believes that many more indications will be found for the use of magnesium. [M. O.]

May 25, 1901. (28 Jahrgang, No. 21.)

1. The Limit of the Pupillary Reaction in Chloroform Narcosis. ADOLF FLOCKEMANN.

1.—Schleich says that in giving chloroform the pupil must be watched. It becomes smaller as the patient goes under the influence of the drug. Just enough chloroform should be given to keep the pupil a moderate size. Flockemann describes the first sign that the patient is coming to himself as follows:—though the moderately contracted pupil will react when one eye is opened, yet should both eyes be opened, the pupils suddenly become contracted. This he calls the **limit of the pupillary reaction to light in chloroform narcosis**. If the patient is still under the influence of the chloroform, a few more drops are added slowly; if he is almost awake, they must be dropped on rapidly. When the corneal reflex remains throughout the anesthesia, enough chloroform should be given till it disappears. Flockemann believes that the patient will be better off, should this phenomenon be watched. [M. O.]

MUENCHENER MEDICINISCHE WOCHENSCHRIFT.

May 7, 1901.

1. The Symptomatology of Rheumatism (Tendenitis Rheumatica Ocularis.) A. PICHLER.

2. The Diagnosis of Tumors of the Frontal Lobes. HOENIGER.

3. Tuberculous Meningitis with Tuberculosis of the Male Genital Organs. M. SIMMONDS.

4. Action of the Kissingen Carbonic Acid Baths in Heart Disease. LEUSSER.

5. The Bath Cure of Heart Disease. STIFLER.

6. Gun-Shot Wound of the Bladder. B. BAYERL.

7. Treatment with the Ultra-Violet Rays. GOERL.

8. The Extra-Cranial Ocular Manifestations of Syphilis. O. SCHWARTZ.

1.—Pichler reports the case of a man who for 15 years had had frequent attacks of acute articular rheumatism. In the last attack the pain appeared to be localized at the attachment of the tendons to the bones, and not in the joints. In these attacks the eyes became red, swollen and painful. The points of greatest tenderness appeared to be the insertions of the inferior and external recti, finally extending to all the insertions of the muscles of the eye. There was no involvement of the lids and no discharge from the conjunctiva. In addition, the patient had an erythematous eruption upon the skin. A diagnosis was made of **rheumatic tendinitis of the eye**. The treatment of this condition is purely anti-rheumatic. If, which is readily conceivable, the attachments of the muscles of the periosteum to the posterior portion of the orbital cavity should become inflamed, very extensive lesions might be produced. [J. S.]

2.—Hoeniger discusses the diagnosis of lesions of the frontal lobes and reports several cases. The first, a woman of 50, one year after the climacteric, developed melancholia and suicidal tendencies. As there had been some family difficulties the symptoms were ascribed to them. The patient also had slight paresis of the muscles of the right side of the face followed by persistent agrypnia, then vomiting, twitching of the hands and a peculiar staggering gait. Later a left-sided hemi-paresis occurred, and the patient endeavored to make obscene jokes regarding her condition. She then became apathetic, choked disks appeared in the eyes, and tenderness over the frontal bone, and she finally died of exhaustion. Hoeniger believes that the tendency to make jokes is the result of irritation of the motor speech centre. He supports this hypothesis with numerous examples drawn from his clinical experience. A second case, a woman 32 years of age, had slow drawing speech, commencing papillitis, right hemi-paresis with increased reflexes, tenderness over the frontal bone, and a tendency to make jokes. The 3rd case, a man of 54, had paralytic cramps at the age of 51. There was also severe pain in the lumbar region and a feeling as if something were pressing him apart in the middle of his body. Upon examination it was observed that his mind became rapidly fatigued, that the muscles of his body were so weak that he could not rise in bed. Later, that his memory was impaired, and finally inability to walk developed. Commencing papillitis was observed on both sides. It seems unreasonable to suppose that a tumor could be situated in the motor or parietal region with so few localizing symptoms. The disturbance of the muscles of the body, however, appear to indicate a lesion of the brain. It was finally observed that in the epileptic attacks the left side was more affected than the right, and the diagnosis was therefore made of tumor of the right frontal lobe. An operation was discussed, but the patient suddenly developed high temperature and died. At the autopsy a large tumor was found in the frontal lobe, which, upon microscopic examination, proved to be an endothelioma, arising from the under surface of the dura. It could have been easily removed by operation. Hoeniger draws the following conclusions. It is permissible to think of tumor of the frontal lobe if the earliest symptoms are psychical in character, or, if in the course of the disease, psychical symptoms are more pronounced. The diagnosis becomes more certain if there are cerebral atopia, spasms of the muscles of the trunk or disturbance of speech. In addition there may be motor disturbances of symptoms of nervous lesions. [J. S.]

3.—Simmonds reports the case of a man, 24 years of age, who had tuberculosis of the seminal vesicles and tuberculosis of the meninges. The author has collected 80 cases of tuberculous meningitis, 35 in men. Sixteen of these had tuberculosis of the genital organs. He believes that there is probably a distinct relation between the two conditions, and that in cases of acute meningitis the discovery of tuberculosis of the genital organs will be of value in leading to a correct diagnosis. [J. S.]

4.—Leusser has endeavored to show by means of the sphygmographic tracings, that the effect of the carbonic acid baths of Kissingen upon heart disease, is exceedingly beneficial. He reports the histories of 9 cases, illustrated by the tracings. The paper is still unfinished. [J. S.]

5.—Stifler has also attempted to demonstrate the effect of various forms of baths, both the ferruginous carbonic baths, and the mud baths. He concludes by the comparison of various tracings made with the sphygmograph, and by careful studies of the blood pressure with Basch's blood pressure instrument, that the ferruginous baths have a hydrostatic action, and the mud baths a dynamic action upon the system. By hydrostatic action he means the condition of equilibrium between the heart's action and the vessel tone, whilst by dynamic action he implies an increase in the heart's tone and capacity for work. He therefore recommends ferruginous baths for the temporary forms of heart weakness, and also in aortic disease and arterial sclerosis, but in mitral disease and dilatation of the heart the mud baths are probably better. [J. S.]

6.—A boy of 8 years was shot by his brother with a small Flobert pistol, the bullet entering just above the os pubis, and passing down toward the right. There was a considerable amount of urine extruded from the wound, and subsequently there was some edema of the scrotum and penis. Incisions allowed the escape of considerable urine and the bullet was also extruded. The patient rapidly recovered

There was probably an extra-peritoneal injury of the bladder. [J. S.]

7.—Gouli has devised a method by which it is possible to obtain the ultra-violet rays in a state of great purity for the purpose of dermatotherapy. This consists essentially of a small cap containing 2 aluminum electrodes between which several others are introduced for the purpose of causing deviation of the spark. The electrodes are attached to the 2 poles of an induction coil. The cap is placed as close to the skin as possible. [J. S.]

8.—Schwartz concludes his paper upon syphilitic disease of the eye. Choroiditis is atypically disseminated as the result of syphilitic infection. Sometimes there is also a central choroiditis. There may be a fine dust-like obscuration of the vitreous. The retina is frequently not involved, although the choroid is distinctly diseased, but sometimes small dark specks appear in it and we then speak of choroid-retinitis. Typical disseminated choroiditis and areolar choroiditis are not usually present. There may be gummatous formation, and even syphilitic chorioretinitis, and sometimes a chorioretinitis with cloudiness of the papilla, that occurs particularly in congenital syphilis. Central chorioretinitis is rare. It is characterized by a white, or a greenish-white exudate in the macula. Several months to a year after the infection small grayish spots may appear upon the blood vessels. Simple syphilitic retinitis accompanied by hyperemia of the papilla, and involvement of its boundaries is probably the purest form of retinal disease produced by syphilis. The optic nerve may show various forms of inflammation characterized by hyperemia of the papilla or central or peri-central papillitis. Gummatous disease outside the cranial cavity is rare. Sometimes there is neuritic and occasionally central atrophy. Acute glaucoma may be produced by disturbance of the circulation in the uvea. In the treatment of these conditions, especially in those requiring very rapid action of the remedy, Schwartz prefers preparations of iodine given in rapidly increased doses. [J. S.]

WIENER KLINISCHE WOCHENSCHRIFT.

April 18, 1901. (XIV Jahrgang, No. 16.)

1. The Gastro-Intestinal Symptoms of Nephrolithiasis. MAXIMIAN STERNBERG.
2. An Otitic Brain Abscess Cured by Operation. OTTO PFEIL.

1.—Though stone in the kidney is a condition which generally permits of easy diagnosis, the variety, in which gastro-intestinal symptoms predominate, nausea, vomiting, constipation, flatulence, etc., is with difficulty diagnosed. The gastro-intestinal form is not rare, and shows very few, if any, urinary symptoms. After a review of the literature of nephrolithiasis, Sternberg reports the case of a physician, aged 41, who had his first attack of intestinal colic 10 years ago. Three years before this he noticed unusual frequency of urination. Four years after his first attack another occurred, on the right side of the abdomen; followed, the next year, by another still. Appendicitis was diagnosed, but he recovered without operation. Another attack of colic occurred this year, with the passage of a uric acid calculus. After that, all the minor symptoms which had existed for 13 years, disappeared. Sternberg reports two similar cases. In these cases the main symptoms were intestinal. He has also seen cases in which gastric symptoms were most pronounced. The gastric symptoms are anorexia, nausea, vomiting, coated tongue, etc. The intestinal symptoms are always found in attacks of renal colic. Sternberg has studied 20 ordinary cases of nephrolithiasis in none of which intestinal symptoms failed. Constipation and flatulence were always present, with pain. This probably results from reflex irritation of the splanchnic nerves. The arterial tension is increased, and the pain is felt in the iliocecal region, in the ureter; or in the skin upon the level of the tenth rib, reflexly. There seems no doubt that cases of renal calculus exist with no changes at all in the urine. The tenderness over the ureter must be differentiated from appendicitis. Both Roentgen photographs and the fact that the pain grows much less when the lower end of the body is raised will aid in the diagnosis. [M. O.]

2.—Piffel reports the case of a child of six, who had otitis media for over two months. Mastoid operation was performed, but as there were no brain symptoms, the dura

was not opened. Two weeks later unconsciousness followed, with paralysis of the facial nerve, of the right arm and leg, and double neuritis. As a brain abscess had evidently formed, Piffel operated again, through the former wound, opening an abscess in the left temporal lobe as large as an egg. After irrigation, drainage was left in place. The child had collapsed, but reacted after operation. For two months the abscess made little progress toward recovery; after that, however, it healed well. The child has had no cerebral symptoms since, though some otitis media exists from time to time. The diagnosis in this case was simple. Perhaps the abscess would have healed more quickly, had it been opened upon both sides. The prognosis, nowadays, in operation for brain abscess, is better than it was formerly, as over 10% recover. [M. O.]

JOURNAL DES PRATICIENS.

April 27th, 1901. (15me. Année, No. 17.)

1. The Treatment of Eczema. PROFESSOR GAUCHER.
2. The Treatment of Chlorosis by Copper. LIÉGEAIS.
3. Acute Dilatation of the Heart in the Infectious Diseases and Rheumatism. H. HUCHARD.

1.—In eczema the cause and the lesion must both be considered. Professor Gaucher considers eczema a diathetic dermatosis due to auto-intoxication. The exciting cause may be any irritation of the skin, physical, chemical, animate, etc. Menstruation, the menopause, teething, etc., may cause it; or a traumatism, emotion, etc. But it must not be forgotten that eczema is an inflammation, with great congestion of the cutaneous blood vessels. The treatment will be constitutional, for the cause, and local, for the lesion. Constitutional treatment will be necessary in both acute and chronic forms of eczema. It should also be given prophylactically. Lithemic, nephritic, and dyspeptic individuals should take especial care of their skin, and they should observe a strict diet, without ferments, extractives (fish, game, cheese, or bouillon), acids, or alcohol in any form. They should take milk, eggs, green vegetables, little meat boiled or roasted, and fruit. Besides, benzonaphthol can be given as an antiseptic, and laxatives should be frequently employed. The ordinary constitutional treatment of eczema will be alkalies with feeble purgative properties, cod liver oil, iodides, arsenic, etc. The local treatment will consist of water, with perhaps a little boric acid or picric acid in acute cases. A dusting powder may prove beneficial and should be continued after the eczema has healed. For chronic eczema, alkaline baths, tar, lead, or tannin ointment, ammoniated mercury, salicylic acid, nitrate of silver, etc., can be used. Should pruritus also exist, chloral, menthol, and carbolic acid can be employed. For chronic eczema of the scalp, the hair must first be removed, then boric or tar ointment applied under a rubber cap. For eczema of the nostrils, behind the ears, etc., he advises boric or calomel ointment; for eczema of the lips, wet compresses followed by oxide of zinc. Above all tar, mercury, and salicylic acid will prove useful in old chronic cases. [M. O.]

2.—Mendini 39 years ago first prescribed the salts of copper in chlorosis and amenorrhea. Liégeois began to use them 25 years later, especially in chlorosis with cervical lymphadenitis. Only 15 patients, out of 100 cases of chlorosis seen, gave a tubercular history. Of the 85 without tuberculosis, 50 recovered upon iron, and 35 upon arsenic. But the 15 "scrofulo-tuberculous" cases did well upon copper. Following Cervello's experiments in animals, his pupils, Scarpinato and Mercadente, have used copper in cases of anemia with marked increase in the number of red blood corpuscles. Giudicendrea, who has used copper in chlorosis, reports an increase in the hemoglobin and erythrocytes. Liégeois prefers the acetophosphate of copper, which he gives in doses of $\frac{1}{2}$ to 1 cg. three daily. [M. O.]

3.—Huchard has reviewed the work of Henschen upon acute dilatation of the heart in the infectious diseases and rheumatism. Henschen shows that acute dilatation of the heart can occur in acute rheumatism, and reports four cases in which, as no valvular lesion could be found, the lack of resistance of the myocardium permitted the dilatation to occur. Henschen thinks that the mechanical obstruction from valvular lesions has too often been used to explain cardiac dilatation. Huchard agrees with this, but still doubts the occurrence of myocarditis in the acute dilatation of the heart seen in the infectious diseases and rheuma-

tism. He divides dilatation into two classes, the one due to primary atony of the myocardium, to be treated by digitalis, etc.; the other due to secondary atony of the myocardium, following vasoconstriction and arterial tension. It is the latter form of dilatation of the heart that Huchard has found in the acute infectious diseases and rheumatism.

ARCHIVES DE MEDECINE DES ENFANTS.

April, 1901. (Vol. IV. No. 1.)

1. Stenosis and Atresia of the Larynx. VON BOKAY.
2. The Diseases due to Growth. DERSCHIED-DELCOURT.
3. Perinephritic Abscess due to Staphylococci. HALLE.

1.—Vide abstract of the *Deutsche Zeitschrift fuer Chirurgie*, February, 1901.

2.—During growth, the bones are the most vulnerable part of the human organism. While true osteitis may occur, many cases of slight "growing pains," with or without fever, but with no morphological changes, have been observed. Derscheid-Delcourt reports five cases: two cases of pseudo-coxalgia, one in a girl of 8, very large for her age, with little fever, cured in two weeks, though she wore a celluloid bandage for three months or more; in the other, occurring with dorso-lumbar Pott's disease. Rest and bandaging cured both conditions. The third case was osteitis of the diaphysis of the tibia, in a child of 14, with slight lumbar scoliosis, which recovered in a few months. The fourth case was pseudo-Pott's disease, in a boy of 10; and the last case was a rare case in a girl of 15, with congenital dislocation of both hips, who had remained very small. Growing suddenly, distinct striations appeared, from the thigh to the knee, due to her rapid growth. [M. O.]

3.—Halle reports the case of a girl aged 8 years, admitted to the hospital with pain in the abdomen and back, of three weeks duration. She had been hurt in the right lumbar region two months before. No ecchymosis had occurred, but pain persisted. Later this became worse upon walking. Fever appeared, with anorexia, and she grew thin. She took great care in walking to put her right foot down slowly, on account of the abdominal pain, which was constant in the right lumbar region. No ascites was present. The liver reached two inches below the margin of the ribs. As Pott's disease did not exist, purulent perinephritis was diagnosed. Exploratory puncture drew forth greenish pus, containing pure cultures of the staphylococcus aureus. The abdomen was opened through Petit's triangle, and a retrorenal abscess evacuated, with drainage left in. Three weeks later the child left the hospital. Halle says that perinephritic abscess is rather rare in children. [M. O.]

JOURNAL DE MEDECINE DE BORDEAUX.

April 7, 1901. (31me. Annee, No. 14.)

1. Vaginal or Abdominal Hysterectomy for Cancer of the Neck of the Uterus? ANDRE BOURSIER.
2. Pultaceous Angina as a Prodromal Sign of Measles. R. SAINT-PHILIPPE.

1.—Professor Boursier reports the case of a woman of 58, who looked in perfect health. She had had 7 children. For two years she has had frequent micturition, with pain toward the end of urination. Three months ago she menstruated for a month, since when she has noticed pain in the left iliac fossa, radiating down the left groin. Vaginal palpation showed the neck of the uterus to be a hard mass with a large central opening. She refused operation. But three weeks later she returned with another hemorrhage from the womb, and the pain had increased. The ventral and left sides of the vagina had also become indurated. Cancer of the uterus spreads along the mucous membrane, along the uterine muscle, or secondary tumors may appear anywhere in the uterus. In this case it is impossible to decide how much of the uterus is involved. When she was seen formerly, vaginal hysterectomy was indicated. Now larger intervention seems necessary: the lymph-glands in the pelvis, being perhaps already affected, will also need removal. Boursier advises thorough examination under chloroform to decide how deeply the uterus is involved, and then hysterectomy, most probably abdominal, as soon as possible. [M. O.]

2.—In a recent epidemic of measles, Saint-Philippe noticed a pultaceous angina from two to seven days before the measles appeared. He observed it in 15 cases, out of 190 seen. Small white points appeared, isolated, bluish white rather than dirty, with fever and dysphagia. Some white spots are still present when the erythematopultaceous eruption appears on the roof of the palate, with Koplik's sign. In a few cases diphtheria bacilli were found in these throats. These cases of angina have already been mistaken for diphtheria. Saint-Philippe considers this sore throat a distinct premonitory symptom of measles. [M. O.]

JOURNAL DES SCIENCES MEDICALES DE LILLE.

May 4, 1901. (No. 17.)

1. Treatment of Chronic Hydrarthrosis of the Knee. A. BALLENGHIEN.
2. Fracture of the Diaphysis of the Ulna. AD. PLATEL.

1.—Ballenghien reports a case of hydrops articuli in a man of 28. He had already had his left knee treated by ignipuncture, after which the effusion returned. The next year it was again punctured, and again the year later, but it always recurred. Then the right knee became affected. No cause for the condition could be found. The left knee was incised, and irrigated with carbolic acid solution (1-20). For some time he wore a knee support, but has done well without it since. No microbes were found in the liquid evacuated. The right knee, which had been treated off and on, was operated upon three years later, by the same method. He recovered and is now perfectly able to walk. In using carbolic acid irrigation there is always danger of absorption, with poisoning. Should symptoms appear while the carbolic acid is still in the joint-cavity, immediate arthrotomy should be performed. Massage, electricity, and a support composed the after-treatment necessary. [M. O.]

2.—Platel reports two cases of fracture of the diaphysis of the ulna, in adults, from direct violence. After being reduced, massage was employed every three to five days. The splint and bandages were removed, friction rapidly done, and the arm again put into the splint. In from four to six weeks both patients had recovered and were back at work. [M. O.]

LA PRESSE MEDICALE.

May 18, 1901. (No. 10.)

1. Lateral and Circular Sutures of the Veins. G. CLERMONT.
2. Orthoformic Eruptions. W. DUBREUILH.

1.—Suture of the veins was first attempted by Nicaise in 1872, since when it has been done about a hundred times. Clermont reports a case upon which he operated for tubercular cervical lymphadenitis. As he had separated the internal jugular vein, he applied temporary cat-gut ligatures, while he sutured the opposing edges with fine silk. This healed well. Clermont then performed successful venous sutures in rabbits and in dogs. Thrombosis occurred only at the periphery, and the vessel was not obliterated. In 10 days the endothelium had again joined, over the sutured surfaces. The lateral and circular suture can only be attempted in the large veins. A round needle and fine silk are needed. From this now simple operation, it is but a step to suturing the wall of the heart. Clermont thinks that will soon become possible. [M. O.]

2.—Orthoform may produce two separate varieties of eruption, erythema, alone or complicated with vesicles or pustules, and gangrenous eruptions, which are rare. The former may appear even when the orthoform is applied upon healthy skin, not necessarily upon an open wound. They are readily cured in a few days. The gangrenous eruptions occur when varicose ulcers are treated with orthoform. There is much pain. Dubreuilh reports two such cases, both of which recovered after a long time. The fact that the physician would not stop using the orthoform increased the period of duration of the gangrenous eruption. [M. O.]

Original Articles.

THE FATHER RIEGEL MURDER CASE.

By WILLIAM G. PORTER, M. D.,

Philadelphia.

Surgeon to the Presbyterian Hospital.

On the 5th of January, 1901, at 6.30 A. M., at 400 North 8th street, Philadelphia, the dead body of a man was found in the vestibule, resting on a marble floor with marble sides, his arms extended, his head resting on a marble step. His clothing was disarranged; he was without an overcoat; his coat, vest and shirt were pulled up over his arms; his chest, abdomen and back were bare from the waist up. The door from the vestibule to the street was open about 6 inches, the body of the deceased preventing the closing of the door. The temperature varied from 32 to 35 degrees F. As soon as the body was discovered a patrol wagon was summoned, and shortly afterwards it was removed to the Hahnemann Hospital, where the resident physician, on duty at the time, pronounced the man to be dead, and the body was at once removed to the Morgue. It was subsequently identified as that of the Reverend Charles P. Riegel. A post-mortem examination was made about noon of the same day by the Coroner's physician. The body was that of a man about 32 years of age, of approximately 160 pounds in weight and of good muscular development. There were no external marks of violence, and no evidence of organic disease. The brain was considerably congested, the lungs slightly congested, and the kidneys rather noticeably congested, the bladder well filled, and the mucous membrane of the stomach considerably congested. There was a small amount of a dark fluid in the stomach. The contents of the stomach were sour, and there had been some change in the wall by action of the sour contents of the stomach. There was a rather more marked amount of fluid in the intestines. There was an odor of alcohol perceptible in the stomach contents. The liver was slightly enlarged, just a little larger than normal. No chemical analysis of the stomach contents was made. A preliminary inquest was held by the Coroner on the 7th of January, and a certificate was issued from his office that the deceased came to his death from congestion of the brain. The body was interred on the 9th. On the 19th of January the final inquest was held and the verdict of the Coroner's jury then was that the deceased came to his death from opium poisoning. The original certificate on file at the office of the Board of Health was not amended until the day of the trial, in which the certificate was shown in court by the defense. As soon as the body had been identified, detectives were put on the case by the Police department, and it was soon discovered that the watch, chain, cuff buttons, overcoat and money of the priest had disappeared. Suspicion fell on the occupants of the adjoining house (a furnished room house), and on investigation it was found that some of its occupants had disappeared, and that on the night of the occurrence, one of them had purchased a small bottle of laudanum at a drug store in the neighborhood. One of the suspects was arrested in New York, and

other was found hiding in the loft of his residence in Philadelphia. The various missing articles belonging to the dead priest were recovered from different pawn shops, and as a result of the investigation of the police, seven persons, 3 men, 2 women and 2 boys, were arrested, charged with the robbery and murder of the priest, and two more suspects are fugitives from justice, and have never yet been apprehended. The defendants having elected to have separate trials, on the 7th of May, 1901, Jacob Wynne was brought to trial before Judge Stevenson and a jury, charged with murder. Under the law of Pennsylvania, any murder which occurs in the perpetration of a felony, such as rape, arson, burglary or robbery, or results from the administration of poison, is murder in the first degree. Great trouble was experienced in securing a jury, and three days were consumed, and three venires of jurors containing 160 talesmen were exhausted before the jury box was filled. The allegation of the Commonwealth was that the deceased had been inveigled into the furnished room house where he was filled with beer which was later drugged with laudanum; that while he was unconscious he was robbed, stripped, carried out, and finally deposited in the vestibule of the adjoining house, where he was found dead a few hours afterwards; that the defendant had purchased nearly half an ounce of official laudanum, and had himself put it in the victim's beer, and insisted on his drinking the whole of it, and that the deceased had come to his death from opium poisoning. The links in the chain of evidence were skilfully forged by the District Attorney from the first meeting of the defendant with the deceased to the finding of the dead body, the recovery of the stolen articles from the different pawn shops, and the arrest of the defendant while in hiding. The Coroner's physician testified that the death was caused by opium poisoning. The experts summoned by the Commonwealth endorsed this opinion, and swore that the amount of laudanum administered to the priest was sufficient to have killed several persons. The evidence of the leading expert for the Commonwealth was particularly emphatic, and was as follows: "When opium or laudanum is administered for the purpose of destroying life, or in large doses, in the amount that has just been claimed, half an ounce, which half ounce contains, or should contain, if it is the official preparation of laudanum, 24 grains of opium, any subject or individual taking 24 grains of opium in the above named time will have their lives speedily destroyed, and they will present the evidences that the Coroner's doctor pointed out here in his testimony as being the changes produced upon that body. The changes in the patient's, or in the subject's stomach, the change in the patient's kidneys, the change in the patient's bladder, the retention of the urine in the patient's bladder, which is one of the decided evidences that the bladder has been paralyzed, the change and engorgement of the patient's lungs, the change and the engorgement of the patient's brain, the marked engorgement of the lower portion of the brain, at its base; these are all decided evidences of opium poisoning, and I would not hesitate a moment in deciding that this man was killed with opium or laudanum." Question:

"Was there enough laudanum there, assuming it to have been 10 per cent. of powdered opium in strength, to have killed a man?" Answer: "There was enough there to kill six persons." Question: "Enough laudanum in that half ounce to kill six persons?" Answer: "To kill six persons." Question: "When a person dies of opium poisoning the opium is, I understand, absorbed by the system, is it not?" Answer: "The opium or laudanum given to a healthy subject, as this individual was healthy from the description of his own family doctor, and the description of the Coroner's physician who found no evidence of organic disease, and as all the organs of his body were in a good state, the absorption is very rapid. Opium is taken up and carried by the circulation to the nerve centers and the opium is burned up in the system. This is one of the actions of opium. Opium, laudanum, or morphine cannot under such circumstances be detected after death by the most expert chemist in the world in a patient's stomach or intestines. The laudanum is burned up or destroyed in the system and destroys the patient's life. Under no circumstances is it necessary to examine the contents of the stomach or bowels, or the tissues, or any portion of the body. You cannot find the morphine and opium. It is destroyed, and the most expert chemist cannot bring it back, sir." The drug clerk who sold the defendant the laudanum identified him, and swore that but one grade of laudanum was kept in the store, and that was the official. He was corroborated in this by the proprietor of the store. Two of the co-defendants swore that the defendant first suggested giving something to the priest to fix him. He left the house with the avowed intention of procuring it, and came back to the house after a short absence with a small bottle in his hand, emptied its contents into a glass of beer which he gave to the priest to drink, and when the priest only drank half of it, insisted on his drinking the rest of it, which he did. He then gave the empty bottle to one of these witnesses, who, by his orders, destroyed it. The defense claimed that the priest was intoxicated when he was first met by any of the party, that he took them to two saloons, where he treated three of the party and himself to four drinks of beer each, that then at the suggestion of the defendant they all went to the furnished room house, where the priest paid for, and helped to consume with ten others, 24 kettles of beer containing about one quart and a pint of beer each without the froth, and also a bottle of wine. They denied that the priest died of opium poisoning, but claimed that he died of alcoholism and exposure, and that even if laudanum was administered to him it was not given to him by the defendant, but by one of the other defendants, who has not yet been apprehended. The defendant himself was placed on the stand, and, while he admitted the purchase of the laudanum, he denied that he had given it to the deceased, but said it was purchased by him for, and given to, one of the defendants who is still a fugitive from justice, for the relief of a violent toothache. The defense had purchased several samples of laudanum from the same drug store at which Wynne had purchased his, and had them analyzed, and they were declared by the expert chemist who examined them to be only half

the standard strength as directed by the Pharmacopoeia. The principal expert for the defense declared on the witness stand that except for the recovery from the body, of opium or some of its constituents, there are no characteristic signs of opium poisoning found in the body after death, and that those which were described by the Coroner's physician as having been found by him at the autopsy were much more characteristic of poisoning by alcohol than of poisoning by opium, and on cross examination the Coroner's physician himself admitted that the congestion of the various organs which he described might have been produced by alcohol. Great stress was laid by the defense on the condition of the brain, which was described by the Coroner's physician as wet, or moderately wet, and this was claimed by all the experts for the defense to be more characteristic of alcohol than of opium poisoning. In reply to the positive statements of the chief expert for the Commonwealth, that the death was undoubtedly due to opium poisoning, and that no chemist could, after death, recover opium or its constituents from the body, he was confronted with the following quotations from his own text-book on therapeutics. "If a fatal dose has been taken the above symptoms intensify, the pulse becomes slower, respiration is reduced to 5 or 6 to the minute, the reflexes become abolished, and death occurs from paralysis of the respiratory center, or carbonic acid accumulation in the blood. Post-mortem examination may show some of the drug yet remaining in the stomach or intestines, and the internal organs reveal considerable venous congestion, especially the lungs. Alt has shown that after injection subcutaneously morphine can be detected in the stomach. Rosenthal points out that the salivary glands also separate morphine from the blood. In the case of patients who were taking no more than 5-6 of a grain daily the characteristic reaction of morphia could be obtained. Morphine does not appear to be destroyed, or materially altered, in passing through the animal organism. It seems probable, however, that small amounts of the alkaloid are decomposed within the body, while larger quantities escape without change. Morphia is likewise eliminated by the skin and kidneys. Elimination seems to proceed slowly, as morphine has been found in the urine several days after the drug had been discontinued." In rebuttal the chief expert for the Commonwealth testified: "What I have stated in this book is (referring to his text-book on *Materia Medica* and *Therapeutics*) that if an individual takes so much laudanum, takes so much opium, takes so much morphine, and that individual survives the opium poisoning, that you will be able to detect it in the bladder, and in the tissues and organs of the body. But if that patient dies, the opium so taken in the body, in the condition that this subject was in, is burned up in the body and the chemist cannot obtain the opium." The opinion of the chief expert for the defense was corroborated by two other eminent experts. After a rather extended and careful investigation of the leading authorities on the subject of deaths from alcohol and opium, it must be confessed that it is a little hard to decide how far, where one or more lives are in jeopardy, the medico-legal expert is justified in stating positively on the

witness stand that such a death was due to opium poisoning or to alcohol poisoning, where an excessive quantity of both has been taken. In the case at issue there can be no doubt that if the deceased was given 24 grains of opium, that alone would have been sufficient to have caused his death unless he vomited it, or the stomach pump was used. But was the laudanum, which it was alleged was administered to him, of that strength? Three samples of laudanum obtained from the same store at which Wynne purchased his, and analyzed by an expert chemist, contained only half of that amount. It is a fact well known to physicians that there are drug stores where laudanum of several different strengths is constantly dispensed, the standard laudanum for prescriptions, and different strengths for customers who come without a prescription, or who are unknown to the druggist. It has happened to the writer to see a whole ounce of such laudanum consumed by a patient within twelve hours without the slightest anodyne, narcotic or other effect. On the other hand, a man who was intoxicated when he was first met, and no one knows what he had been drinking before, whether malt, spiritous or vinous liquors, and then continued to drink beer for an indefinite time, and is then exposed as this man was, practically on the street, half stripped, with the thermometer ranging from 32 to 35 F., could very readily have lost his life from the alcoholism and exposure. There certainly are no conditions found after death which are absolutely characteristic of opium poisoning. Then, too, while opium and its constituents have frequently been recovered from the body after death, there are cases reported of undoubted death from opium in which the most careful chemical analysis has absolutely failed to discover any trace of the drug. The practice of giving "knock-out drops" to intoxicated, or even sober men, is constantly on the increase in all of our cities, and there is no doubt whatever that many cases in which this has been done are never even suspected. Druggists should be held to a stricter accountability, and no poisonous drug of any description should ever be dispensed without a physician's prescription. The verdict in this case was Guilty of Murder in the Second Degree. A second defendant plead guilty to murder in the second degree, which plea was accepted by the Commonwealth, and a third was convicted of the same grade, with a recommendation to mercy on account of his youth, and the rest of the defendants are either tried, or are fugitives from justice.

COXALGIA.*

A New Form of Treatment, with Report of Cases.

By E. H. COOVER, M. D.,

of Harrisburg, Pa.

This paper outlines a form of treatment curative of and adapted particularly to the early stages of all the coxo femoral inflammatory affections as well as to the distinct arthritic, acetabular and femoral forms of hip joint disease; and proposed as at least of marked advantage in well-developed cases, used

either alone or in conjunction with extension and the other usual procedures.

Until the introduction of the X-ray, the early structural change undergone by the bones involved was largely a matter of surmise, although post-mortem examinations revealed a degree of absorption, necrosis and local thickening, with pelvic distortion and inflammation of periosteal, ligamentous and muscular tissues. The writer believes that the diseased processes could usually be here arrested

Coxalgia.

and the patient be saved great pain and deformity; but if the disease be allowed to progress until the rim of the acetabulum is eroded away, the head of the femur is forced out of its socket and seeks a new home where newly formed bone granulations are massed together, receive the head and form a new socket, with from two to four inches of deformity to the leg, with the consequent formation of pus and leading to tissue destruction, exhaustion and death unless nature is strong enough to arrest these later degenerative processes.

S., aged 17 years, consulted me April 28th, 1900. He was a shoe fuster by occupation and walked two miles every morning and evening going to and from his work. Pain was first noted by him about the first of the preceding January, and in the lower anterior portion of the left thigh and extending to the hip, and much increasing in severity in February, and in March accompanied by stiffness of the muscles of the leg and some lameness. In April his suffering increased to a degree obliging him to remain at home, his rest at night being greatly disturbed by pain. When I first saw him, he had night sweats, a temperature of ninety-nine and a pulse at seventy-six in the forenoon. The limp in his gait was well marked and the adductor muscular rigidity above the left knee was very prominent, this leg was $\frac{3}{4}$ of an inch shortened, the gluteo-femoral crease was raised and nearly obliterated, the muscles of the left hip were widened and elongated, below the femoral crease, the left thigh measured one inch less in circumference than did the right one, pain was greatest at night, and the heel

*Read before the Dauphin County (Pa.) Medical Society.

tap gave some pain in the hip joint but was more severe above the knee anteriorly.

On May 2d, 1900, an X-ray photograph of the pelvis of the boy was taken at the Harrisburg City Hospital, by Dr. Thomas S. Blair. There was some slight penciling done on the flesh shadows of the negative to give contrast to the outlines of the bones upon the photographic print here shown. Observe the great change in the left pelvic bones. The head of the femur is still in its socket, although the rim of the acetabulum is being absorbed and a degree of effusion exists. Careful measurements of the original photograph show considerable inequality between the two sides as regards the pelvic rim, the ischil and obturator foramen and the trochanters major. The radiograph was taken with the face of patient nearest the photographic dry plate. A second one taken six months after treatment begun, showed no effusion and some degree of improvement in the contour of the bony tissues particularly the trochanter major and the acetabulum.

Treatment.—Dr. Keen says: "General treatment is indicated if called for by an enfeebled and tubercular state, but local medicinal treatment is of no value except that which will secure the destruction of the bacilli and the condensation and cicatrization of the newly-formed granulation masses." The tendency of professional thought is now toward attributing all fevers to bacteria and to substances produced in the blood by their growth, such toxins invariably causing fever. It is very plain that we had a progressive microbic disease existing in this boy's left hip for some time, and all are familiar with the fact that when once such disease involves the osseous structures of the hip, it continues usually from one to four years, creating great suffering and deformity of the pelvis and from two to four inches shortening of the affected limb. Where the disease is detected early and the foot is raised above the ground by using crutches and an extension shoe upon the sound foot, and the child given plenty of fresh air and sunshine, most cases do well and in some instances recover with no shortening of the limb. Early drainage also has saved many patients from great and continuous suffering and deformity.

Since cold bathing and sponging and the local application of ice and refrigerating media is of such general use in allaying inflammation, why not give it some consideration in the treatment of coxalgia? Ice is applied to the head in inflammation of the brain, to the chest in pneumonia, to the abdomen in inflammatory diseases of the viscera, and to the pelvis in certain uterine and ovarian affections; then why not apply it to the hip in diseases of the joint? Alfred Stengel, M. D., Professor of Clinical Medicine in the University of Pennsylvania, writing in the *Pennsylvania Medical Journal*, Dec., 1900, says: "The primary object of the cold bath is not to reduce temperature; its value is mainly as a stimulant and supportive. It causes increased force and reduced rate of the respiration, it strengthens and slows the pulse, it reduces temperature, it probably aids in the elimination of toxic products; but, above all else, it stimulates and supports the nervous system. * * * * The theory that is receiving the most support is that the action of cold is not so much to lower the temperature; it is eliminative."

The writer of this paper claims that in hip joint disease the action of cold is to allay inflammation, arrest suppuration, and promote a healthy nutrition. It shortens the stages and lessens the severity of

the disease, and if cases are taken in time, there will be little or no deformity, and the danger of wasting the strength of the body and a fatal issue resulting in consequence is made very remote indeed. It is a rational method of arresting this most formidable disease when it accomplishes so much in inflammatory conditions of other parts of the body. It is not claimed that cold destroys the bacilli, but rather renders them inactive and gives nature a chance to restore broken down tissue. The continued application of cold, like all other methods of treatment, must be carefully watched. If the cold has a depressing effect upon the patient, the direct application of the ice cap must be desisted from and several layers of some fabric or dry paper be interposed between it and the skin. Good judgment must be used and the condition of the patient be always considered.

Now to return to the consideration of the boy, S. Following out the treatment as here indicated, the region of the joint was surrounded with ice caps kept constantly replenished. Great comfort resulted to him from the cold applications, his night sweats disappeared the first week, he slept better, and was more free from pain, and in fifteen days his appetite returned and he was relieved from all suffering and distress, although the knee and heel tap was still painful. July first, a thorough examination showed that the rigidity of the thigh muscles had nearly disappeared and had lessened below the knee, and the limb was more free and easy in movement, the shortening had lessened half an inch, while the measurement below the gluteo-femoral crease had gained half an inch, his face and skin showed that his blood was in a better condition and he was gaining in weight and strength. August first, his leg was its full length and thickness, and he walked without limp or pain. The ice was now continued through the day only, and tonic medication still administered as before. September first, continued the ice daily from 7 A. M. to 2 P. M., permitting short outdoor walks in the afternoon. October first, discontinued the ice as the boy was quite well. *No extension or counter extension* was employed in the case.

The first case I ever placed upon the ice treatment was Miss S., a lady aged twenty-four years. When a child three years old she had disease of the left hip joint that continued about four years and terminated with the leg four inches shortened. With one crutch and a high shoe she got along very well until she was twenty-two years old, when disease began in the right hip, continuing there for sixteen months when the left hip again took on the disease. It continued in both hips for six months, making twenty-two months in the right hip. May first, 1899, she came to me for advice and treatment. A full history of the case would be long and doubtless tiresome; she was, however, in good medical hands at home. She had spent months at seashore and mountains, had had extension and periods of additional rest in bed but was yet on crutches and growing worse. I found her suffering great pain in the right thigh above the knee anteriorly and in both hips, with groins very much swollen and overlaid with large purple veins and the glands much enlarged and painful. Abduction and adduction was not permissible on account of pain in the hips and right thigh, neither could she turn nor lie upon either side. The knee and heel tap were exceedingly painful, the temperature was 102, pulse 98, there were night sweats, anemia, no appetite, disturbed sleep and the urine was nearly half pus in bulk and swarming with bacteria.

After a few days careful watching of the case, and learn-

ing that every treatment familiar to the profession at large had been faithfully tried without avail. I frankly told her there was nothing more to be done unless she consented to a treatment for which I had neither book nor doctor to sustain me. She replied that she would rather return home to Pittsburg dead than to suffer longer, and agreed to the remedy, viz., ice caps applied to the hips and kept there continuously. She was carefully watched, the skin under the ice never being allowed to become deep red, and purple red was prevented by interposing several layers of flannel or newspaper. The treatment soon proved to be very grateful, giving her sleep all night and much relief within fifteen days when she no longer required a night nurse. Temperature was then 99, pulse 78, and the night sweats disappeared. In thirty days she could turn on either side and remain there awhile. In sixty days she threw either leg across the other, could tolerate knee and heel tap better, the swelling in the groin subsided, the enlarged glands became normal, the pus in the urine lessened but continued in smaller quantities up to the seventh month, when, after steady improvement, the ice was discontinued and at nine months she left for home perfectly recovered. A few weeks ago I heard from her. She had been very ill with some throat trouble but the hips remain well.

The third case was one of traumatic hip joint disease. The patient, John B., was aged fourteen years and was tall and slender. September 14th, 1900, he was thrown from his bicycle against the curbing, striking his left hip. He went about his work as usual but in three days developed a temperature of 101, with pulse at 100. For several days the greatest degree of pain was in the left knee joint which began to enlarge, but about the fifth day it was experienced in the left hip and groin which also enlarged and the glands became very painful. This condition continued with some slight changes in temperature until October 5th, when I was called in consultation. He was in bed upon his back, with a pulse of 95 and a temperature of 101, the left thigh flexed upon the abdomen and leg upon the thigh, movement gave great pain in hip and knee, the tissues over the acetabulum were swollen and doughy, the entire left inguinal region hard and painful to touch and the pain in left leg and hip was so great that it was impossible to extend the leg so as to make an intelligent comparative examination of the two limbs. In consultation, the ice cap applied to the left hip was suggested and agreed to by the attending physician and the German parents of the boy. October 8th, I saw him again, when the pulse was 86, temperature 98½, the pain in hip and leg much better, the swelling in hip and groin much reduced, there was less pain and the leg was in a condition to be readily extended. A comparative examination was made and showed the left leg to be one inch longer than the right one and the gluteo-femoral fold lengthened one inch, this lengthening occurring in the hip. From appearance, the head of the femur was resting upon the rim of the acetabulum and at times a sudden pain would come in the hip joint and then extend to the foot. A movement of the limb would give sudden relief as though a nerve was caught and released. Iron tonics were continued in conjunction with the ice treatment. November 11th, the attending physician reported that the ice had been continued until the fourteenth of October, when the pressure against it in the community became so great that it was removed and extension and iron tonics used. The ice had been used for nine days, however, and the boy was looking well, suffered little pain, the swelling around the hip and groin did not return and the thickened condition of the knee joint disappeared. It is my opinion that if ever the parts are entirely restored to physical activity, it will be a long time; but the condition is greatly improved.

Dr. Edward Rosenthal, of Philadelphia, says: "New treatments and new remedies are always successful in the hands of the one who first advised or originated them, when, however, a remedy becomes universally successful its standing is assured." He further says: "If by such work as this we can claim the saving of one life, then we can prove to the world the necessity of our existence and our labors will not have been in vain." So I say, if we can prevent the deformity and suffering of one person, then our life and labor will not have

been in vain; even if it follows that "the accepted facts of to-day may be proven fallacies to-morrow" and that "we live in a transition period in medicine."

THE CITY'S OBLIGATION TO PROVIDE SPECIAL EDUCATION FOR DEFECTIVE CHILDREN.*

By CLARENCE E. MELENEY, A. M.,

of New York.

Associate Superintendent of Schools, New York City.

Public education is the business of the State, and by the State I mean to include the municipalities to which as corporate units the State delegates its powers for educational purposes. Free public education rests on the broad principle of self-preservation. Every child has a right to an education in the rudiments of knowledge and in the fundamental arts of acquiring knowledge and of expression. This statement needs no elaboration or argument. The existence of public school systems in states and cities the world over establishes this truth. The State has the right not only to provide the means of public education, but to compel attendance upon instruction. The Compulsory Education Law of this State reads: "Every child between 8 and 16 years of age, in proper physical and mental condition to attend school, shall regularly attend upon instruction in a school in which at least the common school branches of reading, spelling, writing, arithmetic, English grammar, and geography are taught, or upon equivalent instruction by a competent teacher elsewhere than at a public school."

The law does not compel the attendance of children not "in proper physical or mental condition," but there is no definition to determine what such proper physical or mental condition is. The State has, however, provided and supported institutions for the education of defective children, thus recognizing the obligation to such persons.

Under the subject of "Defective Schools," which I understand to be "Schools for Defectives," the State Superintendent of Public Instruction of the State of New York said in his annual report: "There undoubtedly rests upon the State under the provisions of the Constitution the same obligation to educate and train for citizenship our defective children as those in more fortunate condition. These schools are, in my opinion, strictly educational and in no degree to be considered eleemosynary."

In the last report of the Massachusetts Board of Education the Secretary says: "It is the policy of Massachusetts to make schooling as free for educable children whose defects forbid them from attending upon public day schools as for their more fortunate fellows."

The census of 1890 gave over 97,000 feeble-minded and idiotic persons in the United States; but this does not take into account many who attend public and private schools and for obvious reasons are not enrolled as feeble-minded, but whose intelligence is so low that the usual means of education produce little or no results. One good authority states that there are 100,000 defective children under 21 years of age in the United States, and that less than ten

*A paper read before the N. Y. Academy of Medicine.

per cent. are receiving any kind of instruction or training in schools designed for the education of defectives.

The subject assigned to me embraces a consideration of all defectives; classified as deaf, dumb, blind, and feeble-minded.

There is no longer any question as to the obligation of the State to provide adequate and appropriate means for the education of the blind, the deaf and the dumb. The suggestion to allow persons with these defects to grow up without a common school education by which they may learn to be wholly or in part self-supporting, would be considered in this day and generation nothing less than criminal. There are in the United States thirty-five State institutions for the instruction of the blind; fifty-six for the deaf and nineteen for the feeble-minded. Besides these State institutions there are twenty-nine public day schools for the instruction of the deaf; eleven of these in Chicago; Cincinnati has two; Boston, Detroit, St. Louis and Cleveland have one each. New York has none. Philadelphia has a school for backward children, thus far supported by the Civic Club and the Public Education Association. Councils has now under consideration a proposition to appropriate funds and to have this school incorporated into the Public School System.

So far as I can learn there are only a few schools for defective children in the United States supported by municipalities. Some cities have special classes. The city of Providence has five classes for backward children and several schools of two or more classes each for incorrigibles. Boston has one school for dull or feeble-minded children. Other cities are considering the establishment of such classes. We have recommended the organization of ten special classes, and the collection of information and facts bearing on the subject is now being made. Some of these classes are to provide for truants who need special instruction, and the others are intended for children of such low intelligence as to require special instruction by teachers trained and educated for the purpose.

The marvelous success, after slow and patient, but scientific instruction and training, accomplished in institutions for the feeble-minded is a justification for and incentive to more extensive facilities for such schooling.

The term "feeble-minded" covers a large class of persons ranging from the profound idiot, up through the imbeciles to the class who are slightly below normal, and whose defect is revealed only by the lack of good sense, or the failure to learn in special subjects, or unusual dullness in all the arts of learning.

In every city and in almost every large school there have been found in attendance children whose intellects are so low that the usual methods of instruction and the unusual patience and skill of devoted teachers fail to produce educational results. Such children are to be classed in the middle and higher scales of defectives.

A careful census should be made of all children of school age in the city from four to twenty-one years of age, and all defective children should be classified. Many such children will be found to be neglected and in the streets; many more may be in public and private schools.

One great error in the education of defectives is the neglect to find them out and put them under training at an early age. Many children attend common schools for some years before teachers ascertain that they have mental defects, and often parents keep their defective children out of the schools until compelled to send them under the Compulsory Education Law. If children are defective, the sooner it is found out the better, since a longer period and special means are necessary to give them even a rudimentary education. Even a normal child, if left in a poor home or allowed to run the streets till eight years of age, will scarcely make up for the lack of instruction and appropriate early training. The great majority of them never recover their loss, and drag through three or four grades and drop out at fourteen to go to work or to remain in idleness. Much more does the defective lose in the lack of early training. I would, therefore, have a careful census to find all defective children of kindergarten age and begin their education as early as possible.

In the States of Illinois, Ohio and Wisconsin, means have been provided by which teachers may be sent to defective children in their homes. If this can be done, education may be begun early, in the child's own environment, and the people among whom the defective lives may also be trained how to teach, to manage, and to live with their unfortunate children.

The examination for purposes of classification should be made by experts. After the teachers have discovered children deficient in sense perception or in intelligence, the expert may easily determine the degree and kind of defect. Year by year teachers would become more skillful in detecting defectives, and a scientific system could be established. At the present time it is very difficult for teachers to determine the deficiencies of the pupils.

The necessity for the examination of "suspects" by experts is apparent, from the fact that it is considered a disgrace by parents, friends and teachers to acknowledge intellectual defects, and it is a serious matter to pronounce persons defective except after examination by a technical board of experts. Parents often attribute failure to teach their children to lack of interest, or lack of skill on the part of the school; the reference to such children as dull and defective, by teachers, would only result in attacks upon the teachers, and charges of incompetence.

In my experience of many years in trying to solve this problem of dealing with backward and defective children in the public schools, I have found the greatest obstacle to the establishment of special classes and the appropriate education of such children to be the unwillingness of parents to admit that their children are defective, or to permit them to be segregated in special classes. An attempt was made recently to organize a class of very backward children in one of our large schools by selecting such from several classes of the primary department, and the effort failed chiefly because the parents were not willing to have their children picked out and separated from the regular primary classes, because they felt it would be a disgrace to the children and the parents to be thus stigmatized. Thus through ignorance or sentimentality the children are deprived of an education that might fit

them for useful living, and are allowed to grow up as useless beings to be a greater humiliation to their families in later life, when it will be too late to cover up the shame and possible disgrace.

I once had a similar experience when I discovered an eight-year-old boy, who was deaf and dumb, in one of my schools. I got the parents to consent to send him to one of the Massachusetts institutions for the deaf, but when the time came for his departure, they would not allow him to go, because they were unwilling to acknowledge that they had a deaf and dumb child. Now this is a prejudice which cannot be easily overcome. If, however, we could quietly grade defective children and place them in small classes in the regular day schools under specially trained teachers, without drawing special attention to them, and allow them to live at home and mingle with their brothers and sisters, much of the difficulty could be overcome.

A complete census and classification of defective children will show two main classes: 1st, those incapable of education; for such special institutions are necessary. 2nd, those who may be educated. The latter class includes: (1) the blind, for whom an institution is the best home; (2) the low grade of feeble-minded, also needing special schools; (3) the deaf and the higher grade of feeble-minded, who could live with their parents and be taught in special classes near home; (4) the highest grade of weak children, who could be taught in special classes by the public school teacher in the regular day schools. (5) There is still another class known to the teacher as dullards; these, when classed with the normal children, usually fair poorly, often fail of promotion, and leave school as soon as the law allows. This class may be backward in a particular subject or may be slow or generally dull in all studies. In many cases the dulness is due to causes that might be removed by scientific treatment, or by special sense training, or by the use of special means or methods of training. Provision should be made for the expert examination of all such cases, an exact diagnosis of the defect or ailment, and an appropriate treatment. There are two main reasons why such differentiation should be made, and why special schools and classes should be established. First, The interests of the unfortunate pupils themselves; Second, the interests of the normal children, and of the teachers, whose entire time is required for the instruction of large classes of average children entrusted to their care. The improved results in the regular classes, to be accomplished after the elimination of defective children, would more than pay the cost of rooms, appliances and teachers of the latter class. Says one authority who has spent many years in trying to solve this problem: "It means success and victory all along educational lines, if untrammelled by defectives; but defeat which will lead to tedious and endless readjustments, if teachers are forced to continue the impossible task of dragging normal and abnormal up to a common standard."

If defective children are to be excluded from the common schools for their own good and for the sake of progress of the average children, what should be done with them? Of course, it cannot be supposed that such children can be taught in their homes except by specialists. The ordinary home does not

possess adequate facilities for instruction of the normal child, much less then can the abnormal child thus be taught. Should the parent be compelled to provide private education for such children? There can be no contention as to the right of a parent with means to so educate his child, and upon such the Compulsory Education Law cannot lay its hand. But we must not forget that the great mass of such children belong to parents who have no means with which to provide private instruction. In such case the duty falls upon the State or the city, as a means of self-preservation and defence, on the same principle that justifies free public education. Children of this class growing up in ignorance are sure to become public charges and inmates of asylums, whereas, patient, and, if need be, expensive instruction and training may produce persons capable of self-support and possessed of a sense of virtue and of morality.

There remains, then, nothing but the provision of appropriate special schools or classes as a part of the public school system. There are now practically no such schools available for New York children. There is one on Randall's Island containing 130 children, but there are personal objections on the part of most people to sending their children to the island. There is a State institution for feeble-minded children at Syracuse, but that is inaccessible. Most of the New York children of this class are either in asylums or in the public schools, in both instances receiving no adequate instruction; or on the streets in still greater danger and neglect.

We must have special schools. Such schools must be in an environment adapted to special work—where facilities favor the careful study by specialists of all physical and mental impediments to development. There must be trained teachers possessed of human sympathies and parental instincts, such as to draw out all moral elements in the lives of the children; of special skill and power in dealing with the problem of mental development; and of ripe and well-balanced judgment and common sense. Born teachers with added special training are needed for such work. The means of education should be:—not only strong and beautiful personality in the teachers and other persons engaged in the care and training of these children, but also the peculiar objects, scenes, events in life, that will stimulate dormant elements of activity. There should also be means of stimulating the emotions of pleasure, as in music, play and systematic physical activity; also opportunities for training of skill in the making of objects and other manual work. It is not recommended that such children be sent to large institutions. As a general principle, I do not believe in asylums and institutions. I believe in keeping children in their natural environment as much as possible, and in teaching them to adapt themselves to the environment in which they are to live. A child who is deaf, dumb, blind or feeble-minded will have to live with people, and must learn, if possible, how to communicate with them. In institutions where most of the inmates are afflicted with similar infirmities a defective child is removed from the environment in which he will have to live, and has no means of adapting himself to normal conditions. That is not the place or the way to educate him for living, how-

ever well suited it may be to teach him how to live while he is an inmate. These children, while not in school, should be, as much as possible, in the environment of active, intelligent social life.

REMARKS ON THE TREATMENT OF ECZEMA.*

By W. R. INGE DALTON, M. D.,

of New York.

Dermatologist and Syphilographer to the Metropolitan Hospital and Dispensary, Professor of Dermatology and Syphilography in N. Y. School of Clinical Medicine; Dermatologist to the West Side German Dispensary.

A tremendous advance is evident from researches made in the last twelve years, having as their ultimate object the increase of all natural resources of defense, possessed by the economy, against toxic and noxious outside agencies. Even at the risk of being classed among ultra-conservatives—those who ride hobbies, far afield—I still adhere to my theory, enunciated at Atlantic City last June, that the "chyme passing in a hyperacid condition from the stomach into the duodenum entails such increased labor upon it that its contents cannot be rendered sufficiently alkaline for physiologic metabolism." "This acid dyscrasia, I believe to be the inevitable *foens et origo* of the pathological lesions which lead certainly to nearly all diseases of the skin." I am still devoting my energies particularly, to the study of the *vis medicatrix naturae*, which the system holds, and which empowers it to overcome the causes of skin affections, especially eczema. A successful and rational treatment, a thorough therapeutic method, confirm me in my determination to pursue assiduously the same object, viz.: the elimination of the uric acid diathesis, before, and in conjunction with, topical applications, by the use of my tablets—Vide: "The Journal," March 30th, ult. I am watching with great interest the results of serum therapy. While I believe the serum does not kill the germs directly, it acts in a secondary manner by influencing the white corpuscles of the blood to augmented activity. Metschnikoff ascribes their action to phagocytosis. Buchner claims the alexin (the defensive powers of the blood) originates in the white corpuscles. If these theories are correct, then it is of paramount importance that the vitality, strength, and general health be not impaired. These causes may be cold (as shown by Bouchard), heat (as demonstrated by Wyssokowitsch), hunger or thirst (Canabis, Alessi), poisons (Zulzer), ferments of bacterial origin (Charrin and Roger.) Treatment must consist in taking into consideration the general underlying conditions, not forgetting the state of the disease, the necessary attention to any abnormal condition of the other organs, which may aggravate, or continue the inflammation. Those patients suffering from chlorosis, or anemic subjects, should have tonics, such as phosphorus, iron, strychnia, and mineral acids. Above all, a dietary should be strictly enforced—meat, if allowed at all, only once a day. No oatmeal, no strawberries, no sugar, not even in coffee or tea. This dietary is to be adhered to for several weeks. Water, in large quantities, should be drunk every day. Gottlieb favors a milk diet for

some time. The alimentary canal should be kept as antiseptic as possible by means of the administration of (such as I use in my tablets) naphthalin, charcoal, and ipecac. Lately I have been exhibiting ichthyol, combined with arsenic, in the so-called strumous diathesis, as follows:

R	Ammon-sulph-Ichthyolat.	drams iii
	Acid-arseniosi	gr. iv
	Glycyrrhizae	q. s. et ft. Pil. No. 180
	M. Sig. 1 or 2 after each meal.	

Those cases where the surfaces are excessively influenced by inflammation (vesicular forms) should be treated by removing all causes of it. Water, for bathing purposes, in all eczemas, should be prohibited, as far as possible, unless rendered alkaline. A good lotion for the bath is soda-bi-carb., one part to fifty of water. All irritants, thermic, chemical or mechanical, scratching with fingers, the secretions from sweat, the use of soaps, etc., should be attended to first. If there are scales or crusts, an oleaginous application, such as olive oil, after hot water and lotion of green soap, may be used. Of course, if the eczema is caused by parasites, or is of the form, called by Unna, *Eczema-schorrhoeicum* (undoubtedly caused by micro-organisms), such as pediculi, the itch-insect, or the trichophyton, a germicide is demanded, such as kerosene oil, salicylic acid, sulphur ointment. A 5% ointment of chrysarobin and pyrogallol, or ichthyol, or tar preparations, in the squamous varieties, if there is not much secretion, ought to be exhibited. Finally, those etiologic factors, springing from neurotic conditions, anemia, leukocythemia, constipation, etc., or, whether the cause be local or external, internal or general, should be completely regulated, and appropriate remedies prescribed. I give my tablets in all forms of eczema.

SKIN GRAFTING BY MEANS OF FREEZING, WITH REPORTS OF SOME CASES.

By GASTON TORRANCE, M. D.,

of Birmingham, Ala.,

During my service as resident physician in the Pennsylvania Hospital it was my privilege to see a number of cases with large areas of denuded epidermis, due to operation, burns, ulcer, etc. While casting about for some convenient and simple method of skin grafting without using a general anesthetic, freezing with ethyl chloride suggested itself. The following cases will illustrate the operation:

CASE 1.—Wm. H., colored, age about 30 years, was admitted on September 10, 1899, with severe burns of the right arm and slight burns of the chest. Almost the entire circumference of the arm from the shoulder to the finger tips was burned. When I went on duty in the ward to which he was admitted, on October 1st, the wounds of the chest had healed, but the arm was a mass of raw granulation and was discharging freely. The arm was thoroughly washed. One of the thighs was shaved and sterilized and then washed with alcohol to remove all oily substances. An area about the size of a silver dollar was frozen on the thigh, with an ethyl chloride spray and a round section about the size of a silver half dollar was removed with a sterile razor and immediately applied to the arm while frozen. During the process of thawing it became "glued" to the wound, and in a few moments had become closely adherent. Several grafts were put on at this time. Some green protective strips were applied over the grafts and the arm enveloped in a piece of lint covered with boracic

*Delivered before Manhattan Clinical Society, May 3rd, 1901.

ointment. The dressing was changed on the third day and the grafts found to be doing nicely. In making the section a portion of the corium was removed with the epidermis. Several graftings were made after this. The patient was discharged on November 24th with the arm perfectly healed and without any scar tissue having formed.

CASE 2.—E. M., white, age 45 years, was admitted October 31st, 1899, with recurrent carcinoma of the breast, having submitted to amputation about a year previous to this time. There was a cauliflower-like growth involving an area about six inches square. This was removed the following day and the skin brought together as closely as possible, leaving a large uncovered space. About three weeks later I applied three grafts taken from the thigh and using the same dressing as in the above case. All grew nicely, and when she was discharged December 27th, the wound had completely healed over. I saw this case six months later, and there was some evidence of a recurrence, but the grafts stood out as healthy islands of skin surrounded by the unhealthy carcinomatous tissues.

CASE 3.—R. B., white, age 8 years, was admitted December 11, 1899, with quite severe burns of the neck and upper part of the left arm and slight burns of the face. When I took charge of her on January 1st all of the wounds had healed except those of the neck and deltoid region. Two weeks later three grafts were applied to the neck. At this time it was noticed that some scar tissue had formed, causing slight contraction of the tissues of the neck. During the night following the operation the dressing was rubbed off and only one of the grafts "took." Several others were applied at a later date and a good result was obtained. There was very slight contraction of the neck, notwithstanding the fact that some scar tissue was in evidence when the grafts were first applied.

CASE 4.—D. C., white, age 21, was admitted September 8th with large specific ulcers of the left leg and groin, the one in the groin following bubo. The patient was put on mixed treatment, and his general condition improved very much and all ulcerated points healed kindly, except one place on the leg about midway between the ankle and knee. It seemed almost impossible to heal this up. About the first of December I put on a frozen graft, and when he was discharged December 21st the whole ulcer had healed over.

In my estimation this method has many good points. It is painless. It enables one to cover considerable areas at a sitting and dispenses with the use of a general anesthetic which must be used in the Thiersch method. It seems especially applicable where the surrounding tissues have become degenerated as in ulcers and malignant diseases, as the newly formed skin apparently partakes of the character of the graft. Some of the advocates of the Thiersch Method hold that it is better to remove only the epidermis. I believe that the cases I have observed have been benefited by the transplantation of some of the true skin. This method is very simple and can be carried out as well in private practice as in a hospital. With a healthy granulating surface every graft should take. I have only seen one failure which was due to the dressing being pulled off in the case of the child, Case 3. I am indebted to Dr. R. G. Le Conte for the privilege of reporting the above cases.

A Case of Prolapsus of Unusually Long Duration.—P. I. Gundegger presented before the Society of Hospital Physicians of St. Petersburg (*Bobritskaya Gazeta Bolnikov*, Vol. XII, No. 10) a patient, 45 years old, who suffered from dyspnea dependent on emphysema and diffuse bronchitis. There was also a sclerosis of the peripheral arteries. On the second day of admission to the hospital the patient was awakened at night by an erection of the penis which in spite of various methods of treatment has been persisting for 16 days. The patient denied venereal excesses or disease of the genitals, nor was there any disturbance of the urinary organs. [A. R.]

REPORT OF A CASE OF COMPLETE RIGHT OCULO-MOTOR AND COMPLETE LEFT TRIFACIAL PARALYSIS.*

By C. A. VEASEY, M. D.,

of Philadelphia.

Demonstrator of Ophthalmology in the Jefferson Medical College
Assistant Attending Ophthalmic Surgeon to the Jefferson Medical
College Hospital Ophthalmologist to the Methodist
Episcopal Hospital, etc

The patient I have exhibited before the section this evening presents the somewhat unusual condition of a complete oculo-motor paralysis on one side and a complete trifacial paralysis on the opposite side, and has the following history:

J. S., an Italian, 25 years of age, consulted me first on the 13th day of March 1901—about five weeks ago. Seven weeks before he had observed some difficulty in seeing well, together with deep seated ocular pain, and visited a hospital dispensary for advice. His eyes were examined and no lesions other than a refractive error being found he was given a mydriatic for refraction. Two weeks later, the pain growing worse, instead of better, he went to another dispensary for examination, where the notes of his condition show no internal or external ocular changes, though at this time there is no record of any accommodation tests having been made. Had they been made, it is probable they would have revealed some weakness of the right ciliary muscle. Four days before my examination, or six and a half weeks from the beginning of the ciliary pain and the dimness of near vision, there appeared a slight divergence of the right eye together with some drooping of the lid and dilatation of the pupil. At the same time there was diplopia, loss of sensation on the left side of the face, some difficulty in passing the urine, a soreness and "pulling" at the back of the knees which made walking painful, considerable vertigo and some headache which, though by no means marked, was worse at night. There was also a history of slight staggering at times and inability to keep on the feet very long at one time. This last symptom was especially annoying to the patient as he was employed as a caretaker in a pool room. At the time of my examination there was partial oculo-motor paralysis on the right side which, according to the patient's statement, first began four days earlier, but which did not become complete until between three and five days later.

The pupil was moderately dilated, gave no reaction, and accommodation was entirely abolished. There were no fundus changes and visual acuity equalled 6/22. The left eye showed no involvement of the internal or external muscles and the pupil reacted promptly to light, convergence and accommodation. The Westphal-Piltz orbicularis reaction was absent. Visual acuity equalled 6/15, there being a moderate hypermetropia in each eye, and the fundus was normal. There were also no changes from normal in either of the visual fields.

The whole left side of the face supplied by the trifacial, including the conjunctiva and cornea, as well as that portion of the mucous membrane of the mouth and nose supplied by distribution from the same nerve, were found to be totally anesthetic, severe scratching with a sharp instrument of the bulbar and palpebral conjunctivae producing no reflex movement whatever. Further examination showed some impairment of the right patellar tendon reflex with the left normal.

The patient stated that his general health had always been fairly good until the beginning of the above series of symptoms. He denied having been inoculated with syphilis, but acknowledged that he had soft chancre ten years before and many attacks of gonorrhoea. He had never been under any course of treatment. There was also a vague history of eczema which may have been a syphilitic eruption. The urinary examination was negative.

Believing that nothing but multiple lesions could produce such diversified symptoms, and that in all probability they were syphilitic in character, the patient was placed upon mercurial inunctions and rapidly increasing doses of

*The patient was exhibited and an abstract of the history read before the Section on Ophthalmology of the College of Physicians, April 16, 1901.

potassium iodide. He is now taking 180 grains of the latter in 24 hours and the right lid presents a small amount of upward movements, though there are no other changes in his ocular condition. His general health is very much improved. The bladder symptoms, the soreness and "pulling" at the back of the knees, the vertigo, the headache, the staggering gait have all either disappeared or diminished in intensity.

Dr. Wm. G. Spiller very kindly made an examination of his condition from a neurologic standpoint a few days ago though the patient had at this time been taking large quantities of mercury and potassium iodide for a month, and reported that the diminution in tactile and pain sensation amounted to complete loss in the inner portion of the territory innervated by the left trifacial nerve, but to partial loss near the limits of this territory. The anesthesia is sharply defined by the median line of the face and implicates the left side of the tongue in its anterior portion. The motor portion of the left trifacial nerve is as much implicated as the sensory portion, and there is marked paresis of the left muscles of mastication easily perceived when the patient places the hands over the masseters and makes slight chewing movements. When the mouth is opened the jaw moves to the left. Voluntary movements of the jaw to the left are normal, but movement to the right is impossible beyond the median line on account of paralysis of the left external pterygoid muscle. When the tongue is protruded it is carried to the left because it is pulled towards the left in the direction of the jaw. Taste is lost on the anterior left side of the tongue through preserved normally on the right. There is no implication of either facial nerve. The left knee jerk is distinctly prompter than the right. No Babinski reflex is obtained on either side and the absence of this sign and the weakness of the limbs indicates that the central motor tracts are not much implicated.

From a study of the symptoms and their course, both before and since the institution of treatment, it is believed that the case is one of cerebro-spinal syphilis with meningeal involvement at the base, probably most marked in the interpeduncular space and over the pons, and involving principally the right oculo-motor and the left trifacial nerves.

NOTE.—Since the above notes were written the patient has been under treatment for two months with complete disappearance of the ptosis, marked return of power in all of the ocular muscles except the inferior rectus and ciliary muscle and return of sensation and motion in the larger portion of the area described as affected. It is interesting to observe that the order in which the paralyzes of the ocular muscles appeared was as follows: ciliary muscle, inferior rectus, superior rectus, internal rectus and levator. The order of returning strength has been the opposite, that is, levator, internal rectus and superior rectus. The inferior rectus and the ciliary muscle are as parietic as ever.

PHOTO-MECHANICAL REPRODUCTION.

By B. H. BUXTON, M. D.,

of New York.

Instructor in Bacteriology, Cornell Medical College, New York.

Every photo-micrographer wishes, sooner or later, to have his best pictures reproduced for publication, and some general knowledge of the various processes by which this is attained, must be of interest to him, and may be of some use in enabling him to make an intelligent choice of the process most suitable for his requirements, and in impressing a sense of his extensive knowledge on the minds of his publisher and printer.

By photo-mechanical reproduction is understood those methods by which the final prints are obtained in a printing press without the direct action of light upon them. Silver, platinum and carbon prints are therefore excluded by this definition; and indeed these processes, although undoubtedly giving the finest results, are, on account of the immense amount of manual labor required and consequent

expense, of no value where large numbers of impressions at a reasonable rate are desired.

Before the days of photography there were three methods in use of reproducing pictures. In speaking of them the present tense may as well be used, as they still linger to a certain extent, though probably doomed to final extinction, except for special purposes.

I. Wood Cuts. Relief Printing.

The pictures are translated by hand on wood to a series of lines or dots of equal intensity, but varying in number and thickness according to whether shadows, half-tones, or high lights are to be represented. Between these lines the wood is cut out and the printing is done in relief; that is to say, on inking over the surface, the ink remains on the lines and dots and an impression can be taken on paper or other suitable material. The lines and dots can always be observed on examining a wood cut closely.

II. Lithography. Flat or Surface Printing.

The lithographic stone is a porous limestone found in a faultless quality only at Solenhofen, in Bavaria. The surface of the stone is polished, the drawing traced on it with a fatty substance containing soap, say, for example, potassium stearate, and the surface is then treated, etched, as it is called, with a solution of gum arabic in weak nitric acid. Where the lines are traced the nitric acid combines with the potassium and the liberated stearic acid forms an insoluble calcium soap with the calcium of the stone. The chemical reaction may be expressed by the equation $2K^+ H^+ O^- + 2HNO^+ + CaCO^+ = Ca (C^{11}H^{17}O)^2 + 2KNO^+ + CO^+ + H^+ O^-$. The calcium stearate being partially derived from the stone itself, adheres very closely to it, and being a fatty substance, will take fatty ink when this is rolled over it.

Gum arabic is composed of potassium and calcium arabinates and on addition of nitric acid is decomposed into potassium and calcium nitrates and arabinic acid; the latter remaining in solution in an excess of nitric acid. After drying out, however, arabinic acid changes to metarabinic acid, which will not dissolve in water. On the bare parts of the stone, therefore, as the gum and nitric acid solution dries up, the arabinic acid sinks into the pores of the stone and closes them, changing to the insoluble metarabinic acid. The surface is now damped and the bare parts, since the pores are here hermetically sealed, remain moist for a considerable time, and therefore repel a fatty ink, whilst the lines of the drawing being of a fatty nature will repel the water and remain dry, so that after inking over the surface an impression corresponding to the lines of the drawing may be taken. The drawing can also be made on paper and transferred to the stone. Except for the transfer, however, the processes are precisely similar.

III. Copper Plates. Deep or Intaglio Printing.

For intaglio printing the lines or dots which are to compose the picture have to be sunk below the surface of a copper plate, so that each line is represented by a furrow. In engraving proper these furrows are cut into the plate by hand; in etching chemical means are used for the same purpose. Nitric acid will corrode copper, but has no effect

upon resinous substances. A copper plate, therefore, is covered with a resinous varnish, and the picture traced in lines with a steel point in such a way that each stroke of the point lays bare the copper. On applying nitric acid the bare places are etched in, the parts covered by the varnish being left in relief. On printing, the ink is dabbed in, filling up the hollows. It is then wiped off from the parts in relief and the impression is obtained by the paper taking up the ink lying in the hollows, more or less according to their depth. By this process the shadows can be printed deeper and the high lights lighter than by either of the preceding ones, giving better contrasts and a brighter picture.

Coming now to the modern photo-mechanical processes, it will be well to explain at the start that they depend on a change which takes place in certain soluble organic substances when mixed with bichromate of potassium or ammonium and exposed to light, by which they are rendered insoluble in water. Gelatine—soluble in hot water—glue, gums and egg albumen, soluble in cold water, are susceptible to this action of light and are all made use of in various processes.

The bichromates themselves have no action on these substances, but on exposure to light are reduced to chromates and chromic oxide, the latter being still further reduced with liberation of oxygen, which, combining with the organic matter, renders it insoluble. The reaction takes place as follows:

It is evident, therefore, that if a metal plate be coated with bichromatised gelatine or other soluble organic matter, and exposed to light under a negative, the bare shadows of the negative will allow the light so to act on the sensitive layer below as to reduce the bichromates and cause them to render the gelatine insoluble in hot water, whilst the high lights not being affected can be washed out, leaving the plate bare in the high lights, but covered in the shadows. If now some fluid which has the property of eating—etching—into the metal plate without affecting the gelatine be applied it will attack the uncovered parts, leaving the covered parts in relief. In other words, shadows are left in relief and the high lights hollowed out, or vice versa if a positive has been used instead of a negative.

Now, however, comes the difficulty of reproducing the half-tones of a picture. If the original be made up of lines or dots as in a pen and ink drawing, in which the shadows are represented by thick lines, the high lights by very thin and the half tones by lines of varying thickness between them as follows:

Diagram 1

there is no difficulty in representing the half tones on a sensitive surface, since in the negative

these lines would remain completely bare, whilst there would be a thick deposit of silver on the intermediate spaces. On the sensitized metal plate, therefore, after exposure, the intermediate spaces would wash completely away, the resulting print in relief, consisting entirely of black and white lines, would represent the half tones exactly as in the original.

In the case of a negative taken from a painting or from nature, however, the half tones are homogeneous, not being represented by lines or dots, and if the negative be laid on the surface of a sensitive metal plate, the following diagram shows what would occur on exposure:

Diagram II

After exposure the surface to the right of A, a movable point depending on the length of exposure, would be insoluble, and to the left of A would remain soluble, so that on washing over with hot water, the plate would appear thus:

Diagram III

and after etching thus:

Diagram IV.

so that on printing in relief the shadows and deeper half tones would come out dark, while the high lights and lighter half tones would be white. In other words, the half tones would be lost and the print appear black and white without any gradations between. In order to avoid this and enable the half tones to be preserved the picture must be translated into lines or dots, grained in fact, and this must be done whether the printing is to be in relief, on the level, or in intaglio.

I. RELIEF PRINTING.

Theory.

If a glass plate ruled with very fine cross black lines, be interposed between the subject to be copied and the sensitive glass plate in the camera, the resulting negative will show these lines on it as clear glass, breaking up the surface into a multitude of minute dots on which the light will act and on which silver will be deposited during development. If the glass screen were laid actually on the sensitive surface, the dots would all be of the same size and the picture would not show, but when the screen is placed a short distance away the light spreads according to the amount admitted through the meshes.

Rays, therefore, coming from the high lights of the subject spread much and produce large black

dots on the negative, whilst those coming from the shadows hardly spread at all and produce dots varying in size according to the depth of the tone. Between the black dots are white lines: very thin and minute in the high lights and gradually thickening throughout the half tones to the shadows. On printing from such a negative by contact on the sensitized surface of a metal plate the effect is of course reversed, and the picture may be represented by diagrams 5 and 6.

Diagram V. Surface View

Diagram V. Side View.

The light having been able to act fully through the screen lines of the negative, on which they are represented as bare glass, the bichromatized gelatine or other matrix beneath them is rendered insoluble, so that on etching the lines remain in relief, whilst the etching fluid attacks the dots which have been protected from the action of the light.

Printing is then done in relief, the network of lines of varying thickness preserving the half tones. On examination of the resulting print with a pocket lens the lines and dots can be resolved. The lines in the high lights appear as dots, the reason for which can be appreciated on examining diagram 5. In the deeper shadows the screen effect of dark lines and white dots is more evident.

It is found that the shape of each dot is exactly that of the aperture of the lens, so that if diaphragms with square instead of round holes are used, the dots are square instead of round, and the appearance would be as in diagram 6.

Diagram VI.

By means of square apertures the corners are better filled up with light than with round ones. In practice, however, it is found that where much light passes through there is overlapping with the round diaphragms (see diagram 5), so that the high lights are sufficiently and better filled in with these than with square ones. It is usual, therefore, to make the first part of the exposure with a round stop in order to fill up the high lights; the lens is then capped and a square stop put in for the remainder of the exposure, the effect of which is to brighten up the half tones by cutting out the corners. Stops of various other shapes are also used, but for illustration the above mentioned are sufficient.

Screens are ruled so many lines to the inch; from

75 or 80 for the coarsest, up to 200 or 250 for the finest. As the screens become finer more care and skill are required in etching and printing, so that when quick work is wanted and common paper used, as for the daily papers, a screen of 80 lines to the inch is the usual one. For magazines and similar publications about 125 to 150 lines. Above 150 lines the printing can hardly be done satisfactorily along with the letter-press, and special plates on special paper usually have to be prepared.

The ruling is done with a fine diamond point, and the lines filled in with a black pigment.

PRACTICE.

Since the process worker, as he is called, starts from a positive picture it is usual to supply him with a silver print of the subject to be reproduced. This is pinned up on the flat board of a copying camera, a long focus, 14 to 16 inch lens selected, and the screen set up in the camera 1-16 to 1-32 of an inch in front of the sensitive plate for the negative. Special holders are made which contain both the screen and the plate, and the former can be moved backwards and forwards by a rack and pinion arrangement. The finer the screen the nearer it must be to the plate.

Diagram VII.

For taking the negative, dry gelatine emulsion plates are specially manufactured, but the wet collodion process affords better results with less trouble and expense, and is usually preferred. The only drawback to the wet plates is the long exposure necessary, about four times longer with the screen than without it, so that the film is liable to dry out.

The negative is developed, fixed and intensified pretty much in the usual way, and may then be taken into the light and examined through a pocket lens. If good the dots will appear clear and distinct without any fuzziness around the margins, whilst between them the glass shows perfectly clear.

The next step is to prepare the metal plate, which may be of copper, zinc or brass. Copper gives the best results and is more generally used than either of the other two. The surface of the copper plate, even if this is bought machine polished, must be thoroughly hand polished with charcoal just before coating with the sensitive solution. There are numerous methods of preparing the bichromatized organic substances for the sensitive coating; albumen, gelatine, etc., being, or having been used, but all may be disregarded with the exception of the enamel process, which has glue for its basis and which is rapidly ousting all the others for ordinary work. From among the many formulas for the solution, the following may be taken as an example:

Fish glue	3 oz.
Ammonium bichromate	120 grains
Water	10 oz.

As the bichromatized substances are not sensitive

to light until dry, the solutions may be made up in full daylight and will keep for a week or so in a cool place, though after a time the bichromates are liable to undergo spontaneous decomposition. The solution, after being filtered through absorbent cotton, is flowed over the plate and, as an even coating is absolutely essential, the plate is put in a machine called a whirler—a very simple affair—and dried gradually whilst spinning round over a gentle heat from a gas stove. The drying must be done in a yellow light—a yellow shade over the window is sufficient—and as soon as the plate is cool it may be exposed to sunlight or strong electric light in a printing frame under the negative. As the progress of the printing cannot be watched, it requires a good deal of experience before exposure can be rightly timed, but three to five minutes in a strong sunlight is usually sufficient. Generally speaking, the quicker the printing the better the results. The plate is next taken out of the frame in a yellow light and washed under a gentle stream of water for a minute or two to get rid of the glue which has not been acted upon by light. The picture will now show up faintly and may be brought out by treating with a weak solution of gentian violet, which will stain the glue more or less deeply according to the thickness of the film, and the experienced eye, with the aid of the pocket lens, can judge if everything is right up to this stage.

Burning In.—The next step is to burn in the glue so that it will adhere closely to the plate, and not lift up whilst the etching is going on. This is done by holding the plate face up in a pair of pincers over a small gas stove, and the burning in is continued until the plate assumes a rich brown hue, the picture coming out clearly on account of the brown color showing more or less according to the thickness of the enamel, as it is now called, on the surface. The back of the plate is then coated with paraffin to protect it from the etching fluid, the plate is allowed to cool and is ready for etching.

Etching.—For zinc plates the etching fluid is nitric acid, but it will be sufficient to describe the process for copper plates, with which ferric chloride is used, ferrous and cuprous chloride being formed whilst the copper is being etched away, the following representing the chemical action:

A tray is half filled with the etching solution and the plate is laid in it face up. The action commences at once and about 15 to 30 minutes is sufficient to complete the etching, during which the black precipitate of Cu^2Cl^2 , which is constantly forming, should be occasionally brushed away with a camel hair brush, and the plate should be carefully examined now and then with a pocket lens to see that the etching is not being carried too far. The lines in the high lights must not be allowed to disappear altogether or there will be no support for the paper on printing and a smeary look will be the result. The plate is then washed under the tap, dried, mounted on a wooden block, and is ready for printing in relief, either on special plates or along with the letter press.

II. FLAT OR SURFACE PRINTING.

Photo-lithography and Collotype.

The principle of both these processes is the same in that certain parts of the surface for printing from are so prepared that they will take fatty ink from the roller, whilst other parts will repel the ink, but the methods of arriving at this result are entirely different in the two processes.

Photo-lithography is more suitable when large plans, etc., in relatively small numbers are required, whilst collotype is the best for small pictures and large editions. The former method of reproduction, therefore, is not likely to be chosen by the photo-micrographer, and it will be sufficient to mention that the process is essentially similar to that already described under lithography, the only difference being that instead of tracing the lines with a fatty soap, the stone is covered with bichromatised glue or gelatin and exposed under a negative. Where the light acts the glue becomes insoluble and remains on the stone after washing, whilst on other parts it dissolves out. The surface is then etched with gum arabic and nitric acid solution to close up the pores of the bare parts and dried. On damping, the insoluble glue quickly dries and takes ink, whilst the rest of the surface remains moist for a considerable time and repels ink.

If homogenous half tones are to be reproduced the exposure can be made under a negative taken through a screen as in the enamel process; or the stone, instead of being polished, can be roughened with fine emery powder, converting the surface into a number of fine points. Between these points the light coming through the negative will not be able to act with so much energy as on the points themselves, so that the glue here will wash away, the insoluble points appearing larger or smaller according as the light has been able to act with more or less intensity. In this way the modulations from shadows to high lights can be preserved.

Collotype is a very valuable process for the photo-micrographer, producing prints almost equal to those of silver and platinum, but the expense is greater than in the screen half tone process, since much greater care is required in the printing, so that the number of copies produced in a given time is far inferior, although this can be remedied to a certain extent by preparing a large plate with several pictures on it, by which means a dozen or more can be taken together. The impressions cannot be taken along with the letter press except by double printing and special plates on special paper must be prepared as a rule.

(To be Continued.)

On the Influence of Acids on the Secretion of Gastric Juice.—A. Sokoloff (*Bohnitchnaia Gazeta Botkina*, Vol. XII, No. 18) performed experiments on a dog with a gastro-duodenal fistula, which established the following facts: Under normal conditions the maximum secretion of gastric juice takes place during the first two hours, when it diminishes gradually, ceasing altogether at the 5-6 hour. This diminution of the secretion of gastric juice is due to the accumulation of hydrochloric acid. The latter, when in excess, inhibits the secretion, while lactic or butyric acid greatly increase it. [A. R.]

Plague in Australia.—"It will be seen at last that careful attention to the more commonplace details of municipal sanitation during the absence of disease, alone affords a reasonable prospect of future safety." Nothing would seem more obvious, and yet it is certain that nothing can be more difficult than to convince the public of this simple principle.

The Report of the outbreak of plague at Sidney, in 1900, a copy of which has just been received by us, is one of the most eloquent appeals for the exercise of sanity in regard to infectious disease on the part of a supposedly intelligent populace, that it has been our good fortune ever to read. Dr. J. Ashburton Thompson, the chief medical officer of the Government, and the President of the Board of Health of New South Wales, had foreseen the epidemic, and had made all possible efforts to secure the observance of reasonable precautions. He watched the result of its effects as they slowly developed, that is, the increase in the popular terror and the willingness on the part of the inhabitants to submit to any measures, no matter how expensive or inconvenient, that were suggested by the most ignorant and blatant of the popular leaders. For some years the Board of Health had been carefully studying the plague bacillus. Stocks of Haffkine's preventive serum were on hand, and even such minute details had been attended to as the possibility of destroying rats and mice by producing in them some infectious disease not communicable to man, such as inoculation with the bacillus typhi-murium, or the organism of Danysz. In the early stages the Board of Health had recommended that in addition to the protection of the human passengers, measures should be taken to prevent the landing of rats, either by some method of mooring, or by the destruction of the rats on ship-board. Means were also taken to destroy them in the wharves, and to put the wharves and their vicinities in a thorough hygienic condition. As usual, these measures were easily applied to the Government wharves and vigorously resisted by private owners, whose wharves, moreover, were found to be in such a dilapidated condition that little could

have been done without destroying them. It was urged that at these wharves a considerable volume of a particularly valuable form of foreign trade was conducted, and that any interference would necessarily result in a severe loss to the entire district. It is questionable whether the entire destruction of these wharves, and the stoppage of this trade, until they could have been rebuilt in a proper manner, might not have been an exceedingly economical proceeding. In the end they were closed in sections and thoroughly cleaned, but long after the epidemic had broken out. The chief criminals, for they certainly deserve this name, because for the sake of saving a little money they exposed the whole city to the ravages of an epidemic, were certain wharf companies and firms that are named in the Report.

Haffkine's prophylactic inoculation was at first employed for the protection of those persons intimately concerned in the treatment of the plague cases, and for the scavengers who necessarily worked in the plague districts. As the epidemic gradually reached its height the populace became more and more anxious to be protected, until they finally overflowed the building of the Health Department, blocked up its approaches and really threatened the stability of the structure, so that it was necessary to remove to larger quarters in the Exposition building. With the fatuity of plague communities, as the epidemic declined and became less severe, all this anxiety ceased, and from thousands presenting themselves every day, the number was reduced to a few hundreds. It may be worth while to mention that among 10,000 persons inoculated, and as far as possible only those likely to be exposed to infection were so treated, only 13 cases of the plague occurred, and these were exceedingly mild, and the patients recovered. Yersin's serum was also employed, but as the supply did not reach the Health Department until late in the epidemic, no very definite results were obtained. On the whole, the conclusion was reached that this serum stimulated the circulation but could not be relied upon as a very active curative measure. So much for the human side of the subject. The other is of extreme interest.

Some form of contagious disease in rats had been observed on one particular wharf before the epidemic, and this gradually spread to other wharves in the district. The first case occurred in a car-man who was working on one of these wharves. The glands in the groin enlarged from below upward. Upon the ankle there was the evidence of an old flea-bite, and the Commission strongly suspected that a flea from one of the diseased rats had bitten the man. It might be mentioned in passing that some sick and dead rats were obtained, and examined bacteriologically, and the plague bacillus found in them, proving beyond peradventure that the epidemic among them was the plague. Accordingly active measures were taken for the purpose of destroying rats upon in-coming vessels, and of destroying those in the city. Of all the measures employed, exposure to the fumes of burning sulphur seems to have been the most effective, and by this means nearly 300 carcasses were obtained from a small steamer that was presumably very little infested. A bounty of sixpence per head was paid for all dead rats brought to the Health Office, and over 100,000 carcasses were thus obtained and burned. This probably had very little effect upon the total number of rats, but as these animals, whenever persistently annoyed, always wander to other places, it probably served to disperse them and perhaps to spread the epidemic somewhat.

A valuable lesson in regard to the management of the epidemic was one suggested by the Board of Health and subsequently carried out. This was the formation of a committee of prominent citizens with sub-committees in all the wards, acting with the Board of Health, the object being to inspire the public with confidence in the measures that were being undertaken, and to educate as large a number of the leaders among the people as possible in their necessity. Such was the plague at Sidney. Conditions there were not unlike those in our own sea-port cities, and are presumably the same as those that must be met among our own populace. It remains to be seen whether, if need occur, we shall rise to the occasion and meet the emergency as successfully and intelligently as it was met at Sidney, despite the defects that were there manifest and perhaps inevitable, or whether the invasion will find us unprepared and criminally unwilling to admit its existence.

Plague on its Travels.—The fact that our Pacific coast is more or less constantly threatened by the approach of plague is shown by the prevalence of that disease in the several countries which border on that great sea. Recently the steamship *Carlisle*

City arrived at San Diego, California, with the report that several of her crew had died of plague en route. This vessel touched at Honolulu, Hawaii. At that time only one member of the crew had died, and the disease does not seem to have been recognized at that port. After she left the Sandwich Islands the disease broke out with renewed violence, resulting in a number of deaths before the vessel reached California.

This event need not be taken as a cause for panic. It should simply be recognized as indicating the need for extreme caution on the part of the health authorities on the Pacific coast. Plague is prevalent now in Honolulu, which is one of our newly acquired possessions, and which is in constant and direct communication with this country. A letter from Surgeon L. E. Cofer to Surgeon-General Wyman, under date of June 8th, gives details of a number of fatal cases in that island. Dr. Cofer believes that the appearance of the disease at this time is a recrudescence similar to what has occurred in other places. Plague is also prevalent actively in Amoy and Hongkong, in China. In fact, the *Carlisle City* sailed from Hongkong, where, apparently, she took on the disease. Bubonic plague in epidemic form has appeared at Amoy, in China, two weeks earlier than last year. This is probably due to the early warm rains following upon a long dry winter. The spread of the disease at that place has been rapid and the fatalities most appalling. According to United States Consul Johnson one hundred deaths per day have occurred in Amoy and its suburbs. In Australia the disease has been studied and controlled, we believe, in a masterly way, to which we refer in another column. To be forewarned is to be forearmed, in the opinion and practice of all trustworthy health officers. We do not doubt that the United States authorities are thoroughly alert to the situation.

Oumikoff's Reaction for Woman's Milk.—In 1898 Dr. N. Z. Oumikoff described a reaction obtained with human milk by means of which not only is the latter distinguished from the milk of any other mammalian, but the period of lactation can also be approximately determined. The reaction consists in a violet-red coloration obtained by the addition of 2.5 cc. of a 10% solution of ammonia to 5 cc. of milk and heating in a water bath to 60 degrees C. The intensity of the reaction bears a more or less definite relation to the periods of lactation, being greater during the latter months. It appears that this reaction, simple and practicable as it is, received but little attention, for neither has it been extensively tried nor have its determining factors been

studied. Recently, N. Ziber made a careful study of the subject with a view of verifying the claims made by Oumikoff, as well as determining the substances in the milk which are responsible for the reaction. The results of the author's investigations are embodied in a paper contributed to the *Archiv. Biologicheskikh Nauk*, Vol. VIII, No. 4. Concerning the external conditions under which the reaction appears, the author found that a higher temperature than 60 C., as well as a stronger solution of ammonia interfere with the reaction. On the other hand, milk several days and even months old, as well as boiled, gives the reaction as strongly as when fresh. The addition of common salts, soda, sodium sulphate or phosphate and ammonium sulphate, does not interfere with the reaction. The same is the case when various acids are added, while absolute alcohol or ammonium chloride prevents its appearance. All attempts to isolate the specific color failed. On precipitation of the solids of the milk by metallic salts or tannin and filtering, the reaction was obtained in the sediment as well as the filtrate. On the other hand, when the milk was distilled the distillate failed to give the reaction. With regard to the substances causing the reaction, it appears from the author's experiments that these probably are the sugar of milk, the iron, and the citric acid contained in the milk. The interesting fact was observed that when dialyzed, not only human, but also cow's milk gave the reaction. This is explained by the fact that in cow's milk the addition of ammonia precipitates all of the citric acid, the latter entering into combination with the lime abundantly present in the milk. Human milk contains less lime and a part of the citric acid is therefore left in solution. On dialysis, however, only a small portion of the calcium of the cow's milk passes through the membrane, while all of the citric acid is dialyzed. The author concludes by stating that not only does the reaction offer convenient means to distinguish human milk from that of herbivora, but it also serves as an indicator of the period of lactation from the fourth to the eighth month. Prior to the fourth, or after the eighth, the reaction cannot be depended upon. In view of such conclusive evidence, it would seem desirable to give the test a wide application and also study it under various pathological conditions.

Leprosy in the United States.—Two years ago a special board was appointed from the Marine Hospital Service to investigate the prevalence of leprosy in this country. This board, consisting of Dr. J. H. White, Dr. G. T. Vaughan and Dr. M. J. Rosenau, has now about completed its report, which we understand is to be submitted to Congress in De-

cember. A preliminary statement has appeared in the newspapers to the effect that the board has discovered about 900 cases of leprosy in the United States. The largest numbers of cases are reported to be in New Orleans and San Francisco. In the latter city the disease is found chiefly among the Chinese. The investigation has not been extended to our new insular possessions, the Philippine and Sandwich Islands, which are both well known to be active propagating grounds for this affection. The report will give a complete census of lepers in the United States, and will contain special histories of several hundred cases, showing the natural history of the disease and its manner of dissemination.

It has long been apparent to thoughtful observers that this country is exposed to the immigration of this disease from several quarters. Leprosy comes not only by way of the Pacific, but also through Atlantic ports. From the Scandinavian peninsula we have probably derived a fair quota of lepers. Possibly more alarm is felt about leprosy as a contagious disease than the facts warrant. It is not and never can be so dangerous an endemic affection as tuberculosis. Instances are cited of lepers who continued in their daily avocations among men. By means of extreme cleanliness and secrecy, the disease is sometimes successfully concealed; so it is just possible that the 900 cases reported by the Marine Hospital Board do not include all the lepers now living in the United States.

The Intraocular Complications of Beri-Beri.—There appears to be considerable room for investigation concerning the microscopical changes that occur in the visual apparatus in beri-beri, and notwithstanding that that disease is indigenous to the East, a study of these changes may be of value in as far as it may assist in clearing up some of the problematical factors occurring in allied polyneuritic affections. At a recent meeting of the Belgium Ophthalmological Society, Coppez reported a case of beri-beri, in which the visual acuity had been reduced to 1-16, with central scotomata for red and green as well as partially for yellow and blue. Holmgren's test showed normal color perception. The peripheral fields of vision were normal. Ophthalmoscopic examination showed hyperemia of the papillae, full and distended retinal veins, the condition as a whole being a partial retrobulbar neuritis with participation of the macula. Diaphoresis, potassium iodide, strychnine hypodermically, and abstinence from tobacco, resulted in gradual improvement, with restoration of visual acuity to 1-6. It has been observed in Brazil that the oculomotor palsies, nystagmus, amblyopia, and blind-

ness, which result from beri-beri, may be cured by change of climate and the disappearance of the beri-beri. This in itself should be an incentive to neuropathologists to investigate the structural changes occurring in the optic nerve in beri-beri, and, if possible, determine whether and to what extent the papillo-macular bundles are involved.

The Mortality from the Hot Wave.—Now that the returns are all in we can form some estimate of the deadly effects of the recent hot weather. As one journal has remarked, the newspapers during that never-to-be-forgotten period contained lists of the dead and prostrated that looked like reports from some great battle. The *Literary Digest* has collected the returns. The death list for the country at large contains the names of more than 1500 persons. Of these more than one-half (about 800) occurred in New York City alone. Philadelphia came next with considerably more than 200. Boston and New England lost 100; Pittsburg, 100; Baltimore, 90; Newark, 75; Jersey City, 40; St. Louis, 35; Chicago, 30; Cincinnati, Cleveland and Washington, 20 each; and so on in diminishing numbers in smaller or cooler cities and towns. It is a remarkable fact that most of the suffering was in the North. The southern cities were comparatively comfortable, and one newspaper in New Orleans invited northern people to come to that city to escape the heat. A Boston paper at the same time reminded us that "at eleven miles up it is eighty-eight below zero." Both suggestions were lacking in practicability.

It is well to remember that we are still in the midst of the summer, and while we are not likely to have another such phenomenal "hot wave," we are still destined doubtless to have the weather uncomfortably warm. As a people, we have not yet learned to endure our hot summers. Our houses, our clothing and our habits are not suited to them. It remains a grave problem in hygiene how to meet these emergencies, and this appalling death list of 1500 should be regarded in a measure as a reproach to our collective recklessness. Certain it is that the burden of toil and poverty should be lightened at such times by all the devices that can suggest themselves to a humane but too strenuous civilization.

A Locomotor Ataxia Club.—The tendency to form clubs is one of the vital phenomena of our civilization. Men and women nowadays organize themselves into associations for every imaginable purpose. The growth of "trusts" is only a larger application of the same principle. Thus far we have had no "medical trust," and we make bold to express the hope that we never shall have one. But,

if reports are true, our patients are beginning to organize. There has been formed, according to rumor, a Tabetic Association. It is not to be an in-coordinate body, but well organized, and is to offer a prize of \$10,000 for a sure cure for locomotor ataxia. In the present state of pathology we fear the offer is a safe one, but we sympathize heartily with the new club, and can even see ground for believing that some good can come out of it. A community of interest is certainly a vital principle among men, and there is no reason why the victims of posterior sclerosis should not find in one another's society a bond of fellowship that may make the general burden of their infirmity less grievous to be borne. To be sure, we have known some tabetics who could hardly be classed as "clubable" men, but a unity of purpose will do much to mitigate the slight asperities that might arise from social distinctions and individual idiosyncrasies. It is a curious fact that locomotor ataxia is one of the few very chronic affections that constantly appeal to the imagination of doctors and patients alike as having in reserve some latent tendency towards recovery. Many experts refuse to be discouraged by it; many patients linger on in the fond hope and expectancy of cure. Let us trust that these hopes will yet be realized, and that the new club will be an active agent in securing such earnestly desired results.

Typographical Errors.—The editor of the *Journal of the American Medical Association* is to be congratulated. He knows how to acknowledge a typographical error, and to get out of it neatly. This is a rare virtue and much more commendable than the cry of the editorial Pharisee, who claims that he makes no errors and who thanks God that he is not as other men are. A paper devoted to "The Cause, Prevention and Cure of Poverty and Pregnancy" will doubtless excite curiosity until the world reads the editor's graceful announcement that the author meant "Poverty and Degeneracy." This is not quite so bad an error as the one that occurred in an old edition of the Bible (a copy of which is preserved in the Bodleian Library at Oxford), in which the little word *not* was left out of the Seventh Commandment. The few rare copies that were preserved when the edition was suppressed, now command a premium among bibliophiles. Perhaps this will yet be so in the case of our contemporary.

The editor who proclaims that he never makes any typographical blunders is on dangerous ground. With his own types he is likely to be condemned. Thus an editor who makes a specialty of being typographically immaculate, recently made one of his contributors speak of "a hemi-anesthesia of

the conjunctiva of the arms and body." This was a great stretch for the conjunctiva, but as the editor is an eye-specialist, the world probably accepted the statement as authentic. Again, an author recently wrote a paper on Spinal Cocainization, but the title was printed in large letters by this same editor as *Special Cocainization*. Such an error is not strictly typographical—it is, rather, an editor's blunder, for an editor should see at a glance that such a title is a misnomer. The *Lancet* recently spoke of "a sour correspondent" (as some of them really are), when it only meant to say "as our correspondent."

But editors have good precedent in this field. Disraeli tells us (*Curiosities of Literature*, Vol. I) that when Pope Sixtus V. issued his edition of the Vulgate he prefixed to the first volume his bull excommunicating all printers who should make any alterations in the text; but the work was found to be so full of errors (although the Pope himself had corrected the proofs) that scraps of paper containing the corrections had to be pasted over the errata. This should be a warning to our infallible editors who proclaim constantly that they never make a mistake.

The great trouble that can come from a little misplaced comma was illustrated once in a small New England seaport. A clergyman read a notice from his pulpit that "Captain Jones, going to sea his wife, desires the prayers of the congregation." And so may all editors, going to print, desire the forbearance of their readers.

Pulmonary Hypertrophic Osteo-arthritis.—Marie first described this condition in adults, in 1890. In children it is very rare. At a recent meeting of the Medical Society of the Paris Hospitals, (*Bulletin et Memoires de la Societe Medicale des Hopitaux de Paris*, 1901, No. 5). Rendu and Bouloche reported a case which occurred in a boy of 11, who had pneumonia at the age of 4. During convalescence it was noted that his fingers became deformed and the right side of his chest retracted. At 6 years, exploratory puncture was made into the right pleura without result. Now he is tall and thin, with a small head, in contrast to acromegaly. The right side of his face is better developed than the left. His nose, upon which are a few varicosities, is usually red. The right side of his thorax is markedly retracted, and is immobile during respiration, while the left side moves more than normally, to compensate for it. There is also a compensatory scoliosis. There is dulness over the entire right side. The arms are very thin, but the hands are immense, especially the wrists, and the end phalanges of the fingers. His nails are enlarged and curved, and grow rapidly. They resemble a parrot's beak. The ankles and toes are also enlarged. Both knees are enlarged, with some effusion. He walks well but slowly. His extremities are generally cold, but perspire profusely. Pain occasionally appears in the wrists, ankles, and knees. There is neither cough nor expectoration. Such a well marked, pronounced, and persistent case is very rare among children. As a rule the affection is acute and curable. In this case the disease followed its course as in an adult. Röntgen photographs show osteoperiostitis of the affected bones. These cases must be carefully distinguished from chronic rheumatism. The relation to the lung condition is hard to understand. Yet the symptoms of hypertrophic osteo-arthritis first develop with some pulmonary disease of long duration. [M. O.]

Reviews.

Oral Surgery. A text-book on General Medicine and Surgery, as Applied to Dentistry. By Stewart Le Roy McCurdy, A. M., M. D., Professor of Anatomy and Surgery in the Pittsburg Dental College. Cloth, 8vo. pp. 368. The Calumet Publishing Company, Pittsburg, Penna. 1901.

This is not a very satisfactory attempt to prepare a text-book on the subjects in general medicine and surgery of interest to the dentist, without discussing the special pathological changes which occur in, and immediately about the teeth. While the author has undoubtedly brought knowledge and personal experience to his difficult task, he has failed to do justice to his self-imposed duty.

Haste or carelessness in the preparation of a scientific publication is always regrettable; and this volume appears to suffer from one or the other, or perhaps both, of these editorial faults. The proof reading, especially of the technical terms, has been very defective, the selection of topics does not seem always judicious, and the literary style is at times neither clear nor correct. As accuracy is the foundation of science and a necessity in didactic teaching, a new applicant for the favor of professional readers makes a bad impression when it speaks of atersia, acna, feruncle, and tie dolonreaux, and misspells proper names.

A well-informed medical reader will find much of interest in this book; but a dentist, unless he has had the advantage of a thorough course of instruction in modern medicine and surgery, will be confused by many of its statements and fail to gain the definite and exact knowledge which he seeks in its pages. These defects should be corrected in subsequent editions. [J. B. R.]

The Hygiene of Transmissible Diseases; their Causation, Modes of Dissemination and Methods of Prevention. By A. C. Abbott, M. D., Professor of Hygiene and Bacteriology, University of Pennsylvania. Third Edition. Revised and Enlarged. Octavo, 351 pages, with numerous illustrations. Philadelphia and London: W. B. Saunders & Company. Cloth, \$2.50 net.

Progress in the important field to which this book is devoted has been rapid and striking during the past few years, and the present edition contains, therefore, much new matter. The part taken by insects and rodents in disseminating diseases, long suspected, is now established upon a scientific basis. The original plan of the work has been retained in this edition, but special sections, notably on malaria, yellow fever, plague and tuberculosis, have been much enlarged. Naturally typhoid fever occupies a prominent place. Its dissemination by drinking water is fully discussed. We are glad to note that the germ is designated *B. typhosus*, and not *B. typhi abdominalis*, as the latter perpetuates an old error as to the relations of the disease. The increase of typhoid fever in Philadelphia in 1897-8 is discussed at some length, and its connection with accidentally polluted water is pointed out. An equally valuable evidence of this fact is to be found in the change in condition of the so-called Kensington district of Philadelphia, upon the abandonment of the pumping station at a highly polluted point of the Delaware river. We miss allusion to the typhoid epidemics of the late war and any account of the official reports thereon.

Expansion has not only brought us new problems in politics, and ethics, but also very important ones in hygiene, hence the discussion of the newly indicated methods of distribution of yellow fever will attract much attention. Unfortunately some of the more striking of the discoveries were published too late for incorporation into the present volume. No less interesting is that in Porto Rico one of the most prevalent fatal diseases is infection with the intestinal parasite, *Anchylostoma duodenale*. During October, 1899 one thousand deaths were reported from this cause in 57 municipalities. This serious condition probably depends largely upon the use of unfiltered surface water and uncooked food.

The book is a useful addition to the literature of hygiene. It is well written and well printed. In the next edition the index and table of contents should be enlarged. [H. L.]

24th Annual Report of the State Board of Health of New Jersey and Report of the Bureau of Vital Statistics. Trenton, N. J., 1900.

This is an octavo volume of three hundred and ninety-three pages and index, containing the usual statistical matter of such reports. Each county receives separate consideration. Thirty-five pages are devoted to a summary of the source and general management of the public water supplies of the State. New Jersey has been rather fortunate in this respect, good artesian waters being found at a moderate depth in many places. Even at the seashore, water free from all but small amounts of mineral matter and of high organic purity is abundant. Undoubtedly this fact has had something to do with the immunity of these resorts from serious epidemics.

An interesting item is an account by D. C. Bowen, local inspector at Asbury Park, of the "cleaning" of a hotel kitchen, which he had a chance to observe. We have not space to insert his letter, but it states that the cleaning consisted principally in throwing about sixty gallons of hot water on the floor, and sweeping this by common brooms into puddles which were allowed to drain through the cracks into the ground below. The same brooms were used without cleaning for wiping off the table tops. The table legs and brackets were not cleaned.

No report is made concerning food supplies. Possibly this is to be found in another volume or the work is now in charge of another department. [H. L.]

Correspondence.

COLD WATER IN THERAPEUTICS.

By ALFRED GORDON, M. D., of Philadelphia.

To the Editor of the Philadelphia Medical Journal:

A recent meeting of the Philadelphia County Medical Society was particularly interesting, owing to the very important paper of Dr. Simon Baruch, who gave us a very able and scientific presentation of the value of water in Therapeutics.

Your correspondent takes the opportunity thus presented to say a few words in favor of a treatment which in the hands of many authorities and his own, gave the most unexpected and brilliant results.

Nervous diseases among all derive the most benefit from water-treatment. While at Salpêtrière the writer could observe that a great number of patients with various forms of spinal diseases were driven daily or walked to the building assigned especially for hydrotherapeutic purposes. He could see a number of tabetic patients suffering from intense pains greatly benefited by water. He could see a number of patients sent from the remotest places of the country, suffering from various forms of nervous disorders, in which a prolonged medicinal treatment was of no avail, greatly benefited by a daily cold douche. Particular notice was taken by the writer of cases of cerebro-spinal syphilis or syphilis of the cord, in which the cold douche was the most efficacious treatment. As to functional disorders of the nervous system, the number of cases is legion. There is not a single patient with neurasthenia, hysteria or epilepsy, who does not get his daily douche. Experiments were made and the douches were withdrawn for a few days and patients kept exclusively on medical treatment; immediately the symptoms of the diseases returned.

Last year the writer had under his care a boy affected with petit mal. In addition to the general hygienic and medical treatment he advised cold spongings twice a day. The number of attacks diminished and gradually disappeared. The cold water was obnoxious to the little patient and it was difficult to prolong it. The parents suppressed it entirely, but continued the drug treatment. The attacks returned in spite of increased doses of bromides. The cold water was readministered and the epileptic attacks disappeared. The same experience the writer had

in cases of migraine, hysteria and chorea. At the Jefferson College Hospital he has under his care a case of syphilis of the cord. The patient affirms that he cannot do without the cold applications suggested to him; the rigidity and numbness of the legs, of which he complains, become aggravated, whenever he omits the water-treatment for a few days. As to the use of cold douches in other diseases, we have seen in the services of Dr. Lancereaux, in Paris, a very great number of cases of cirrhosis of the liver, due to alcoholic intoxication, of diabetes (fat and thin types), gastro-enteritis, enteritis. Particularly we were impressed with the good results in the first stage of alcoholic cirrhosis of the liver, when there is only congestion of the organ and later hypertrophy. Also in cases of pulmonary tuberculosis developed in alcoholic individuals the general health began to improve, the cough diminished, insomnia and night-sweats disappeared and weight increased. Pure alcoholism without complications, M. Lancereaux treated exclusively with a cold douche of one minute duration over the spine twice a day. Cases of enteritis accompanied by diarrhea he treated with a daily cold douche. As to diabetes we could see marked decrease in the percentage of sugar under the influence of a cold douche.

Dr. Simon Baruch made a very interesting assertion, that a few ounces of cold water act upon the mucous membrane of the stomach as a cold douche. I heard it often from the late Potain. I can corroborate it in the most emphatic way. I remember particularly a neurasthenic Italian, for whom I prescribed a form of "bitters" for anorexia. He could not buy the drug, I advised then to take one swallow of ice water before each meal; the patient's appetite returned as if by magic. I do not affirm that it will do so in every case, but it is nevertheless very illustrative, that cold water acts as an excitant upon the gastric secretions.

From personal experience and that of others, the writer can make the following statement: Water, and particularly of low temperature, is one of the most powerful agents in therapeutics and it is regrettable that it is neglected by many physicians. The writer had the pleasure of listening to the favorable remarks on hydrotherapy of such authorities as Drs. Sinclair, S. Solis Cohen and Musser, and joins his voice to theirs in urging the Philadelphia County Medical Society to take some steps towards promoting the usefulness of hydrotherapeutic applications. The writer is a firm believer in applying natural resources in treatment of diseases.

THE CIGARETTE.

By D. BERRY, M. D., of Wetumka, Ind. Ter.

To the Editor of the Philadelphia Medical Journal.

I was both amused and surprised at Dr. Robinson's defense of the cigarette in your Journal of April 27th. It amuses me to see a defense set up for so worthless an article, and it surprises me that Dr. Robinson will make the statement: "and that cigarettes are in any way more injurious than cigars is positively false." Why is cigarette smoking more injurious than cigar smoking? For the simple reason that 9 out of every 10 cigarette smokers inhale the smoke; while cigar smokers do not. The cigar would be far more deadly than the cigarette, if inhaling were practiced, because the quantity of nicotine in one cigar is probably 20 times greater than in one cigarette. I have made cigarette smoking rather a close study in an off hand way, or I might say practical way. I now have under observation a young man who has just abandoned the habit after smoking them for 10 years or more. He became a neurotic of pronounced type. His complexion assumed that "ashy" sallow so peculiar to the cigarette fiend, and his mental faculties became impaired to such an extent that he was almost incapacitated for business at times. He has now reached a point where that insane desire for "a smoke" (abandoned the habit about 4 weeks since) only comes on once in 2 or 3 days and the improvement in both his physical and mental condition is, to say the least, remarkable. His gain in weight is over 4 lbs., and the complexion is becoming pink instead of "ashy," and the mental balance is assuming normal. The point I wish to firmly impress on Dr. Robinson is that the constant inhaling of a small quantity of nicotine (with its necessary absorption by the delicate mucous membrane of

the trachea and lungs) is far more injurious than large quantities simply taken into the mouth and immediately thrown off. I do not doubt that if cigarettes were simply smoked by the mouth, no harm (practically speaking) would result.

HEMOSTASIS IN AMPUTATION AT THE HIP-JOINT.

By H. A. INGALLS, M. D., of Cincinnati.

To the Editor of the Philadelphia Medical Journal.

Referring to an article on page 1132, your issue June 15th, regarding hemostasis in amputation at the hip joint, I beg leave to state that this operation was reported by Dr. C. S. Muscroft, in a paper read before the Cincinnati Academy of Medicine, March 14th, 1887, and published in the *Lancet-Clinic*, April 2, 1887, the operation having been performed August 10th, 1886, by Dr. Muscroft. Dr. Wyeth is reported as stating that the operation was first reported at Nashville in 1890.

CHAIR OF EMERGENCY SURGERY.

By EDWARD WALLACE LEE, M. D., of St. Louis.

To the Editor of the Philadelphia Medical Journal.

In your issue of March 9th, p. 459, under the head of "Chair of Casualty Surgery" you state that Jenner Medical College is the first institution to establish this branch of practical surgery, etc. I wish to call your attention to the announcement of the "John A. Craghton Medical College," Omaha, Neb., where I have held the chair of "Emergency Surgery" for some time, and I believe I am the first to teach Emergency Surgery in a systematic way.

On the Changes Occurring in Sterilized Milk Depending on the Methods of Preservation.—M. A. Zausaloff (*Bolnitchnaia Gazeta Bolkina*, Vol. XII, Nos. 16, 17, 18) found that sterilized milk undergoes chemical changes even in the absence of bacteria. These changes affect principally the fat and casein. The cream separates out of the milk, a large portion of it turning into butter. When such milk is taken by healthy persons for several days severe nausea, vomiting and general malaise are produced, showing that certain poisonous substances are developed. The chemical changes depend on light, air and temperature. If the former two are admitted to the sterilized milk, the chemical alterations take place very rapidly; more slowly when under such circumstances the milk is kept in a cool place, but when both air and light are excluded it remains unchanged almost indefinitely. To accomplish the latter the author recommends (1) that the milk for sterilization be perfectly fresh, especially in hot weather; (2) that the bottle containing the sterilized milk should be free from air; (3) that the milk should be kept in a dark place. Regarding the utility of sterilized milk in infant feeding, the author, after an experience with 265 children, comes to the conclusion that healthy infants from the age of one month thrive on it quite satisfactorily. Gastro-intestinal disturbances are no more frequent than in the breast-fed babies. In children suffering from gastro-intestinal diseases sterilized milk acts almost as a specific cure. The milk should be diluted one-half with water and 10-12% of sugar added. In the case of infants unable to digest such milk, the latter should be diluted with an equal quantity of artificial gastric juice. [A. R.]

A Contribution to the Pathological Anatomy of the Cardiac Ganglia.—G. S. Koulescha (*Bolnitchnaia Gazeta Bolkina*, Vol. XII, Nos. 15-17) found marked and fairly constant degenerative changes in the cardiac ganglia in cases of typhoid fever and membranous enterocolitis. In the nerve-fibers he demonstrated disintegration of the chromatin bodies, chromatolysis and changes in the form of the nucleus; achromatolysis, shrinkage and swelling of the protoplasm and, finally, necrobiosis of the nerve cells. The stroma presented interstitial changes characterized by acute inflammation accompanied by round cell infiltration and multiplication of the nuclei in it as well as the endothelium of the capsule. These changes, the author believes, are functional in origin. [A. R.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Dr. Thomas R. Neilson has been elected assistant clinical professor of genito-urinary diseases at the University of Pennsylvania.

The Lancaster Board of Health.—The following officers were appointed to constitute the Lancaster Board of Health: Dr. D. R. McCormick, James Shand, Dr. Oliver Roland, R. M. Reilly and Dr. E. T. Prizer.

Berks County Medical Society.—At a recent meeting of the society, Dr. L. Thompson read a paper on pertussis, which was discussed by Drs. Keiser, Stryker, Pelk, Kurtz, Bachmann, Beuhley and Frankhauser. Dr. Frankhauser read a paper on some uses of adrenalin, having used it in a number of cases of conjunctivitis, iritis, scleritis, to relieve the congestion, in enucleation to control the hemorrhage prior to cutting the optic nerve and blood vessels, as an injection of ten drops into the tonsil prior to excision. In all those cases it has acted as a powerful astringent, blanching the parts, for several minutes or until the operation is about completed. In hypertrophic rhinitis it acts as an astringent and relieves the congestion for some time after the application, when it again returns.

Dr. Simon Flexner's Report of the Plague in California.—Dr. Flexner's comprehensive report concerning the plague in California, appearing in the *Alumni Register* of the University of Pennsylvania for June, 1901, should be read by every physician. It will be remembered that on account of the controversy which had existed between the State officials of California and the national authorities, the Secretary of the Treasury appointed a Medical Commission to proceed to San Francisco and to determine the presence or absence of plague in that city. The personnel of the Commission consisted of Professor Simon Flexner, of the University of Pennsylvania; Professor L. F. Barker, of the University of Chicago, and Professor F. G. Novy, of the University of Michigan. Upon the arrival of the Commission the municipal authorities cheerfully and promptly rendered material assistance, and no time was lost in becoming acquainted with the sanitary conditions of the city. A description of "Chinatown" in San Francisco can be well appreciated by Dr. Flexner's own words, "The quarter comprises fourteen blocks in the heart of San Francisco and contiguous to the business portion of the city on one side and the newer residence portion of the city on the other. Trolley cars pass through the streets of the quarter and a lively pedestrian traffic continues all day and late into the night. While the white population mixes only slightly, except clandestinely, with the Chinese, yet the central position occupied by the quarter brings about mingling of the races to a much greater extent than is usual between native and foreign populations in other cities. The habitations of the Chinese are for the most part poor in character; the houses which they occupy are commodious and were evidently respectably built; but as they have long ceased to be subject to repair and as the Chinese have a peculiar passion for subdividing rooms and subletting compartments, they have long since fallen into a state of wretched neglect and insufficiency as measured by air capacity. If to these conditions is added an indifference to filth that is most apparent in, if not limited to the Oriental, a fair, although scarcely adequate idea of the local conditions of habitation may be obtained. To quote from the report of the Commission: "The dwellings of the poorer classes of Chinese were found to be here, as they seem to be everywhere, shockingly unsanitary. In places there is marked overcrowding; the rooms are small; they are often entirely devoid of light or means of ventilation, and nearly always insufficiently lighted and ventilated; many of them are filthy; some of them, especially those situated in basements, are damp and emit a foul stench. These faults in sanitation are not confined to the tenement houses of the Chinese; on the contrary, in the rear of, or over or under some of the more pretentious business buildings are to be found sleeping and living apartments which are most objectionable from a sanitary point of view. The Chinese in San Francisco, however, on account of higher wages and the abundance and cheapness of food, are in

better condition than their countrymen in the East. Some of the difficulties encountered by the Commission were the temperament and social habits of the Chinese, especially deterring being their superstition concerning the presence of death and their incomparable secrecy. A bacteriological laboratory completely equipped for the study and cultivation of bacteria was soon established, and the conclusions reached by the Commission not only established the existence of plague among the Chinese of San Francisco, but evolved the important fact that a complete bacteriological study is absolutely essential for the establishment of a definite diagnosis. As soon as the report of the commission was in the hands of the Secretary of the Treasury and of the Surgeon General of the Marine Hospital Service, the municipal and national health authorities co-operated, and took steps to eradicate the disease. The efficacy of these steps will be awaited with interest, and are especially important in that they may prevent the dissemination in the United States of this insidious malady, by the migratory Chinese.

Vital Statistics of Philadelphia for the week ending June 13, 1901.

Total mortality	668	
	Cases.	Deaths.
Inflammation of the appendix 3,		
bladder 2, brain 12, bronchi 5,		
heart 3, kidneys 24, larynx 1,

NEW JERSEY.

Acute Contagious Conjunctivitis in Newark.—The *Medical Record*, under the title "Pink Eye in Newark," states that a New York daily paper publishes a despatch from Newark, N. J., stating that the small boys who bathe in the more or less dirty waters of the river, canal, and bay, are suffering from sore eyes. The paper says that "physicians call the disease 'cayri neticito,' and they say it is caused by a germ in the water. It is contagious." The compositor must have had conjunctivitis himself who twisted the word into such awful shape. Would it not be better still to call this affection by its scientific ophthalmological term—acute contagious conjunctivitis?

NEW YORK.

Mortality in New York State.—During May the deaths in New York State numbered 10,327, nearly 500 above the average for that month during the past five years.

Warning Regarding R. G. Stearns.—The publishers of the magazine *Success* have issued a warning to the effect that a man calling himself "R. G. Stearns" is awindling physicians in various cities through offering them a clubbing combination of from eight to twelve magazines at a cost of \$4 to \$5. He uses a form of receipt with the name of the publishers printed on it, which they state is wholly unauthorized. He has operated in Scranton and Reading, Pa., in Utica, Syracuse and Albany, N. Y., in Detroit and elsewhere.

Enteric Fever in Brooklyn.—Only four cases of enteric fever were reported in Brooklyn in two weeks, which is a much smaller number than was reported during the corresponding time of former years.

St. Vincent's Hospital of New York City has received the sum of \$25,000 by will of the late Mrs. Matilda B. Brown.

Hospital Attendants Arrested.—Two attendants of the Manhattan State Hospital, New York, have been arrested and held in \$2,000 bail to await the action of the Grand Jury on a declaration made by a coroner's jury that they had been responsible in hastening the death of an insane patient by ill treatment.

The New York State Board of Charities.—At a meeting held in Albany the New York Board of Charities adopted a resolution calling upon the city of New York to erect a new and modern hospital to take the place of Bellevue Hospital, and that the salaries of the staff be increased.

NEW ENGLAND.

Scarlet Fever in Beverly, Mass.—It is reported that upwards of a dozen cases of scarlet fever of the malignant type have recently occurred at Beverly, Mass., and that several deaths have resulted.

Storage Charges on a Leg.—Several years ago a wealthy resident of Concord, N. H., lost a leg, which he had preserved in alcohol and stored in a drug store. When he died, twelve years later, the leg was taken from its jar and interred with his body. Shortly after the druggist who had cared for the leg sent to the trustees of the estate a bill for \$3,450 for services rendered in connection with the amputated limb. This bill the trustees refused to pay, and the druggist brought suit. The case was tried in the Superior Court; and a jury brought in a verdict for the plaintiff for \$1,979.16.

WESTERN STATES.

Medico-Legal Society.—Mr. Jean Robert Moechel, a Kansas City chemist, has recently been elected a member of the Medico-Legal Society. The society is an international organization of chemists who make a specialty of poison cases and other cases which require expert testimony in court.

Diphtheria in Cats.—Cats are said to be dying in great numbers in Chicago from a throat trouble said to be diphtheria.

Hospital for Consumptives at Fort Bayard, N. M.—The latest reports concerning the hospital for consumptives, which was instituted under the direction of Surgeon General Sternberg, at Fort Bayard, N. M., about a year ago, show that there are 149 patients now undergoing treatment. This establishment is the only one of its kind in the country devoted to military and ex-military patients. Of the 149 patients mentioned sixty-four are soldiers who have been discharged from the army.

Death of Dr. Harkness.—Dr. Henry Wilson Harkness, the noted scientist, died at San Francisco on July 10, after a long illness. Dr. Harkness was prominently identified with the Academy of Sciences, and was the president of that body from 1887 to 1896.

Dr. Hiram P. Merville, of Milwaukee, Wis., was unanimously elected surgeon of the Wisconsin Veterans' home, at Waupaca, in place of Dr. Noyes, deceased.

Poison in Hospital Milk.—It is stated that poison has been found in milk furnished to patients in the Chicago County Hospital. Samples submitted to the City Chemist,

upon analysis, showed the presence of formalin in sufficient quantities to do considerable harm to the patients. The discovery of this adulteration may lead to the criminal prosecution of the venders.

The Ohio State Pediatric Society at its recent meeting in Cincinnati, elected the following officers: President, Dr. D. S. Hanson, Cleveland; first vice-president, Dr. T. V. Fitzpatrick, Cincinnati; second vice-president, Dr. J. H. McCassey, Dayton; and secretary and treasurer Dr. J. V. Kofron, Cleveland.

To Study Plague.—Sergeant Kinyoun, in charge of the marine hospital in Detroit, Mich., has been detailed by the supervising surgeon general of the marine hospital service to proceed to Japan and China on a tour of inspection of the work done by the marine hospital service there. He will investigate contagious diseases, and particularly the plague.

SOUTHERN STATES.

Franklin Square Hospital.—The new hospital connected with the Maryland Medical College will be known as the Franklin Square Hospital, instead of the National Temperance Hospital.

The Death of Dr. Le Conte.—Death has removed from scientific ranks the scholar, teacher and scientist, Dr. Joseph Le Conte. Of an illustrious family, five of which gained distinction during the last century in various scientific fields, Professor Le Conte was born in Georgia in 1823. He was a pupil of Agassiz, at Harvard, in 1850. From that time on he made rapid strides towards fame, and in 1869 was appointed to the chair of geology and natural history in the University of California, which he held until his death. His numerous works on geology, biology, optics, education, art, philosophy, theology and aeronautics have met with universal favor among scientists.

Dr. T. L. Hopkins, of Charleston, W. Va., has been appointed clinical physician at the Maryland Hospital for the Insane at Catonsville.

Dr. E. T. Rucker has been elected city physician for Manchester, Va.

Chimboroya Hospital.—The charter for the Chimboroya Hospital has been obtained and building will begin in the fall.

CANADA.

Meeting of the Ontario Medical Association, held at Toronto, June 19th and 20th. (Continued). First Day—Afternoon Session. President's Address: Dr. McKinnon delivered a very able address on the opening of the afternoon session. He considered that it was a great honor to be elected president of this, the largest and most influential medical association in the Dominion of Canada. Having referred to the success of the meeting so far, he proceeded to contrast the state of medicine at the beginning of the last century with that of the present, and compared the vast advantages we to-day possess over those of one hundred years ago. Anesthesia, antisepsis, asepsis, vaccination, the anti-toxin treatment for diphtheria, the discovery of the bacillus of tuberculosis were mentioned, and he looked for the dawn in no far-distant day, of that grand and glorious day when we can say to the world that tuberculosis and cancer can both be cured. He deplored the growth in the employment of new proprietary remedies, and thought that harm was being done to the medical profession by manufacturing firms making up pills for neuralgia, for malaria, etc. He considered that the literature and drugs sent out to medical men by these manufacturing houses had become an intolerable nuisance. The electric belt man, the Christian Scientist, the advertising cancer-curer, the osteopath, and many other such like fakes which hang on to the skirts of medicine, he scored most unmercifully, and regretted that the public press, both secular and religious, opened their columns freely to these fulsome, untruthful, and sometimes immoral advertisements, because they pay well. There was great danger to the public in permitting Christian Scientists, the "pray-for-hire-healers" and the "Dowieites," impudently undertaking to cure infectious diseases, such as diphtheria, scarlet fever and smallpox—diseases which they are unable to recognize, and he thinks that we have come to a point where toleration and forbearance become criminal. The 2,500 medical men in Ontario should have in

fluence enough to obtain from the Legislature an amendment to the Medical Act that will put an end to this trifling with human life. He directed attention to the delay that occurs in securing admission to the asylums for people, the subjects of acute mania, and thought it was high time the necessary steps in this department in the practice of medicine should be simplified.

Pulmonary Tuberculosis—Its Treatment in Special Sanatoria.—Dr. J. H. Elliott, Medical Superintendent of the Sanatorium at Gravenhurst, read this paper. Speaking generally, it may be said that from fifty to seventy per cent. of the incipient cases are restored to health, while of all classes from fifteen to thirty per cent. are reported cured or arrested, in sixty to seventy per cent. a marked improvement is noted. The first thing noticeable after entering the sanatorium, in most cases, is an improved appetite, a gradual gain in weight, and a decline in evening temperature. With this improvement night sweats disappear without medication, the cough and expectoration noticeably lessen, and the patient sleeps until morning. The principles generally adopted are: First, a continual life in the open air, with rest or exercise as indicated; second, a liberal, suitable diet; third, medicinal treatment according to indications, and to a great extent symptomatic; fourth, hydrotherapy; fifth, a strict medical supervision of the patient's daily life.

Speaking of the "rest-cure" in febrile cases, the object is to reduce muscular exertion to the least point consistent with the ingestion and proper assimilation of a good diet. Referring to medicinal treatment, with a hygienic life, pure medicines are required. The various tuberculins and serums are being used both in America and Europe, with the prospects of yet securing a specific for those cases where mixed infection is absent. Constant supervision of the patient is the most important point in which the sanatorium treatment must necessarily differ from that adopted by the general practitioner. Living, as he does, with his patients, adopting their mode of life, having his meals in common with them, the physician is enabled to individualize the treatment, and though on broad lines the patients all receive the same treatment, each one has to be studied in detail, and the indications met accordingly. The chief point, under all circumstances, is that the patients, wherever they may be, live prudently, and be under the care of an intelligent and firm physician.

Dr. Price-Brown referred to the advisability of sending patients for sanatorial treatment, and stated that we have for every disease places to send our patients—hospitals throughout the length and breadth of the land, except for tuberculosis. Having recently been at Ashville, N. C., he described the treatment which he had seen carried on in that institution.

Dr. John Hunter, Toronto, deprecated sending these patients long distances away from their homes, which was formerly the custom, but is not so now. He hoped to see the time when there would be a large number of these institutions established in this country. Dr. Elliott, in reply, emphasized the point that there should be no exercise when the evening temperature is above ninety-nine degrees; it may be permitted in the morning if it reaches one hundred or one hundred and a half, but not in the evening.

Vaccinal Protection Against Smallpox.—Dr. P. H. Bryce, Toronto, the Secretary of the Provincial Board of Health, presented this paper. In the introduction to his paper he expressed the belief that although the practice of vaccination against smallpox had existed for a century, there never was a time since it was formally accepted by the profession, when there was so much expressed scepticism as there was to-day on the part of the laity with regard to its protective qualities, and never a time when the profession has been so indifferent as to impressing the necessity of its proper performance upon the public. In Ontario, between 1898 and 199, there were but twenty-two recorded deaths from the disease. He made special reference to the art of vaccination and the quality of the lymph, and thought five separate insertions should be made in each case. The quality of the lymph was very important. He thought that a medical man going out from college did not receive sufficient practical instruction on this most important subject.

Mr. I. H. Cameron discussed Dr. Bryce's paper and stated, as a matter of fact, he had no hesitation whatever in seeing a case of smallpox himself, nor would he object

to any member of his family seeing it. If he knew that they had sufficient protection through vaccination. He warned the profession against laxity in dealing with this most important subject.

Empyema.—Medical Aspect.—This subject was introduced in a well prepared paper by Dr. Ferguson, London, who said that the treatment of this condition was essentially surgical, and that the medical aspects of the disease were limited to a consideration of its pathogenesis and prophylaxis. He considered that the conditions of non-purulent or primary effusion are indispensable to an understanding of the pathogenesis of empyema. He gave a description of the pleura and discussed the bacteriological aspect of purulent pleurisy, which he divided into four classes. First, those due to pneumococci; second, those due to streptococci (and staphylococci); third, those due to the bacilli of tuberculosis, and fourth, those caused by saprogenic organisms. In nine cases, extending over eleven years in his practice, three were diagnosed tubercular, three meta-pneumonic, two due to the streptococci, and one undetermined. The prognosis varies with the micro-organism present, the pneumococci being the most benign. It is the only variety of purulent empyema that may possibly yield to treatment by mere aspiration, especially in children. Tubercular empyema is usually mixed infection. The prognosis here will depend upon the general condition of the patient, and the character of the mixed infection. We therefore see the importance of the bacteriological examination; as in any other debilitating disease, supporting and tonic treatment is essential. With the advent of pus, surgical means must be adopted.

Surgical Aspect.—Introduced by Dr. J. L. Turnbull, Goderich. When the presence of pus is determined it should be evacuated at once, as there is always the danger of the abscess bursting into or through the chest wall, or even through the diaphragm and producing peritonitis. Aspiration need not be described; remember not to remove the fluid too rapidly. In this, as in an ordinary abscess, it is not necessary to open at the most dependent point. The preferable way, and the one which Dr. Turnbull always uses when a diagnosis of pus is made, is to remove a portion of a rib; an inch and a half may be cut out, preferably with the saw, under strict antiseptic precautions. Dr. Turnbull advises washing out every day when pus is offensive, and drainage tube gradually shortened until it can be removed altogether. Where a cavity and sinus remains after this operation, the sinus may become closed and a second empyema established. This requires an Estlander's operation, and one of the best ways is to carefully locate size and boundaries of cavity with a probe, and after dissecting up a flap of skin, be sure to remove enough bone. The hard fibrous tissue beneath the rib, which is always present in quantity there, must be thoroughly removed. Dr. Turnbull advises mopping out with pure carbolic acid, then with alcohol to prevent poisoning, and then with sterilized water, the part being carefully dried. He puts a drainage tube in the most dependent part.

MISCELLANY.

More Surgeons for the Army.—Although 45 assistant surgeons in the army have been appointed there are yet 50 vacancies to be filled under the Reorganization law. The surgeons are appointed directly from civil life and are not required to have seen military service. Examinations will be resumed next September.

Gold Blindness.—Hypermetropic members of the dental profession who are also astigmatic are in some cases liable to lose the power of distinguishing gold-filling from the tooth on which they are working. This form of retinal asthenopia appears to be due to abnormally rapid exhaustion of the visual power, and the trouble is noticed to occur when the eyes have been kept fixed upon a small gold stopping for a length of time, the warm yellow color of the metal tending to exaggerate the preexisting defect. In addition to inability to distinguish the filling from the tooth dentists who present this defect cannot recognize clearly the contour of the hole they are stopping. In the *Canadian Practitioner* for June it is pointed out that age does not predispose to this affection nor does youth exclude it. The primary cause of this particular form of blindness indeed is probably the excess of yellow rays from the gold metal. After a few days' rest the sufferer is enabled to resume work as before, but recurrence frequent-

ly takes place, and the intervals during which work can be carried on become shorter and shorter. The treatment suggested by Mr. L. Webster Fox is, first to correct any error of refraction, to examine carefully into the general health of the patient, and to advise that nothing tight be worn round the neck. The last direction is necessary in consequence of so much dental work having to be done with the head bent. The intense white light which accompanies the fusing of gold plates contains an excess of yellow rays, and it is suggested that this constitutes the causative factor in the disorder.—*Medical Press and Circular.*

Enno Sander Prize.—The Enno Sander Prize consists of a gold medal valued at one hundred dollars and one hundred dollars in cash for the best essay on "The Most Practicable Organization for the Medical Department of the United States Army in Active Service." The conditions of the competition are as follows:

1. Competition is open to all persons eligible to active or associate membership in the Association of Military Surgeons of the United States.
 2. The prize will be awarded upon the recommendation of a Board of Award, selected by the Executive Committee. The Board will determine upon the essay to which the prize shall be awarded, and will also recommend such of the other papers submitted, as it may see fit, for honorable mention.
 3. In fixing the precedence of the essays submitted, the Board will take into consideration—primarily—originality, comprehensiveness and the practicability and utility of the opinions advanced, and—secondarily—literary character.
 4. Essays will consist of not less than ten thousand nor more than twenty thousand words, exclusive of tables.
 5. Each competitor will send three typewritten copies of his essay in a sealed envelope to the Secretary of the Association so as to reach that officer on or before February 28, 1902.
 6. The essay shall contain nothing to indicate the identity of the author. Each one however will be authenticated by a *nom de plume*, a copy of which shall, at the same time as the essay, be transmitted to the Secretary in a sealed envelope together with the author's name, rank and address.
 7. The envelope containing the name of the successful competitor will be publicly opened at the next succeeding annual meeting of the Association, and the prize thereupon awarded.
 8. The successful essay becomes the property of the Association of Military Surgeons of the United States, and will appear in its publications.
- The Board of Award, 1901-1902 is as follows: Honorable William Cary Sanger, Assistant Secretary of War; Brigadier General George Miller Sternberg, Surgeon General, U. S. Army, and a distinguished officer of the line to be announced later. John Van Rensselaer Hoff, President; James Evelyn Pilcher, Secretary.

Obituary.—Dr. Edwin Simmer, at Philadelphia, Pa., July 9.—Dr. John F. Trenchard, at Fairton, N. J., July 12, aged 81 years.—Dr. H. W. Harkness, at San Francisco, Cal., July 10, aged 80 years.—Dr. August W. H. Reen, at Peoria, Ill., July 9, aged 76 years.—Dr. Francisco Ezell, at Fayette, Mo., July 9, aged 54 years.—Dr. Freeman H. Chase, at Bangor, Me., July 11, aged 62 years.—Dr. Richard Gardiner, at Gloucester City, N. J., July 12, aged 51 years.—Dr. Thomas J. Cheatham, at Chesterfield county, Va., July 13, aged 74 years.—Dr. Lewis B. Spencer, at Blackstone, Va., July 12, aged 81 years.—Dr. Edward Hewes, at Frederick, Md., July 15, aged 44 years.

Changes in the Medical Corps of the Navy, Week Ended July 13, 1901.

ASSISTANT SURGEON R. T. ATKINSON, ordered to the Washington Navy Yard, July 8.—July 5.
ASSISTANT SURGEON A. W. BALCH, ordered to the Washash, July 8.—July 5.
ASSISTANT SURGEON J. R. WHITING, detached from the Dixie, and ordered home to wait orders.—July 6.
DOCTORS P. E. McDONNOLD and R. M. YOUNG, appointed assistant surgeons from July 2, 1901.—July 6.
ASSISTANT SURGEON M. V. STONE, ordered to Naval Hospital, Mare Island, Cal.—July 8.
ASSISTANT SURGEON R. T. ORVIS, detached from Naval Hospital, Mare Island, July 20, and ordered to the Pensacola.—July 8.
ASSISTANT SURGEON R. R. RICHARDSON, detached from

the Naval Hospital, New York, and to Naval Hospital, Newport, R. I., July 8.
ASSISTANT SURGEON A. E. PECK, detached from the Pen-sacola, July 20, and ordered to the Asiatic Station as the relief of Assistant Surgeon F. L. Benton.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended July 12, 1901.

High Mortality in British Camps.—Lord Raglan, Under Secretary of State for War, in the course of an announcement stated that the whites in the concentrated camps in South Africa numbered 14,624 men, 27,711 women and 43,075 children. He said also that the mortality for the month of June was 63 men, 138 women and 576 children.

Dr. F. W. Hewitt has been appointed Emeritus Lecturer on Anesthetics at the London Hospital, on his resigning the post of Instructor in Anesthetics which he has held for fifteen years.

The Neurological Society of London met on June 22d, at Manchester, on the invitation of the Manchester members. Professor Dreschfeld acted as President. Specimens were shown by Dr. Bruce, Dr. Judson Bury, Professor Delépine, Professor J. Dreschfeld, Dr. Moore, Dr. Mott, Dr. Orr, Dr. E. S. Reynolds, Professor Sherrington, Professor Stirling, Dr. Trevelyan, Professor Young, Dr. Warrington, and Dr. Williamson. Clinical cases were shown by Dr. Ashby, Dr. Judson Bury, Professor Dreschfeld, Dr. Harding, Dr. Harris, Dr. Dixon Mann, Dr. Reynolds, and Dr. Williamson. In the afternoon the Society was entertained at the Royal Asylum, Cheadle, at the invitation of Dr. and Mrs. Mould and the Committee of Management. In the evening the Society dined at the Queen's Hotel.

Medical Press and Circular.—Dr. Henry Jellett, ex-assistant master of Rotunda Hospital, Dublin, has been appointed editor of the *Medical Press and Circular*, to succeed Dr. Archibald Hamilton Jacob.

Plague in Cape Colony.—A telegram received at the Colonial Office on June 6th gives the following statistics of plague at Cape Town for the week ending June 1st: Fresh cases: Europeans, 2; colored persons, 5; Malays, 9; Indian, 1; Chinese, 0; natives, 3; total 11. Corpses found: Europeans, 2; colored persons, 3; Malays, 0; Indian, 1; Chinese, 0; natives, 1; total, 7. Deaths (including corpses found): Europeans, 2; colored persons, 4; Malays, 0; Indians, 2; Chinese, 0; natives, 2; total 10. The total cases up to June 1st are as follows: Europeans, 173; colored persons, 309; Malays, 48; Indians, 11; Chinese, 1; natives, 142; total, 684. The total deaths have been: Europeans, 57; colored persons, 159; Malays, 35; Indians, 8; Chinese, 0; natives, 59; total, 318. The area of infection remains the same. Seven cases have so far occurred at Port Elizabeth, including 1 suspect.

CONTINENTAL EUROPE.

Professor Hyspolte Gosse, of Geneva, has just died. He was appointed to the chair of Forensic Medicine at the University of Geneva in 1875, which position he held until the day of his death.

The Birth of Sextuplets.—The *Pester Lloyd* is the authority for the statement that the wife of a Greek priest in Deligrad, Serbia, has just had three girls and three boys born. They are all well formed and in good condition. 18 months ago she had triplets. This makes a total of 9 children in a year and a half.

Pasteur Institute, Lille.—From the opening of the Pasteur Institute at Lille, on February 15th, 1895, to January 1st, 1901, the total number of patients treated there has been 1,498, of which four have died of hydrophobia, and of these four one refused, after a few inoculations, to go on with the treatment. The total mortality rate, therefore, is 0.26 per cent.

Persian Superstition.—A physician who has recently returned from Persia, says that the natives still believe that human tears are a remedy for certain chronic diseases. At every funeral the bottling of the mourners' tears is one of the chief features of the ceremony. Each of the mourners is presented with a sponge with which to mop his face and eyes, and, after the burial, these sponges are presented to the priest, who squeezes the tears into bottles, which he keeps.

The Treatment of Anal Fissure.—Before operating upon two cases of fissure of the anus in young women, Professor Tillaux (*Bulletin Medical*, 1901, No. 41) said that it is a common affection, very painful, always necessitating operative interference. An anal fissure consists of three things: (1) the wound, a single, small fissure, radiating from the coccyx to the anus, very superficial; (2) the contracture, a spasmodic stricture, as it were, of the anal sphincter; and (3) the pain, severe and paroxysmal, radiating to the lumbar region. The cause of anal fissure is unknown. The contracture results reflexly from the pain of the fissure. The prognosis without operation is grave, as cachexia develops, with death, perhaps. Before giving chloroform, the patient is placed on one side, ready for operation. Just as soon as she is under the influence of the anesthetic, the two index fingers are introduced into the anus, and the sphincter is dilated. Care must be taken, as death may occur reflexly while the sphincter is being dilated. [M. O.]

1.—Sir R. Douglas Powell in his Cavendish lecture discusses **acute cardiac failure**. The most obvious cause of heart failure is direct injury, excluding, of course, external wounds, as, for instance, the very rare occurrence in which a healthy man during some sudden effort ruptures one of his aortic cusps. The displacement of a clot from a systemic vein, is also a common cause of acute anginal heart failure and is attended with urgent dyspnea, an irregular fluttering pulse, and very variable heart signs. Cases of this class, however, are by no means necessarily fatal. If the clot passes on to the lungs, recovery ensues in a fair proportion and the prognosis in each case must be considered on its separate merits. Next to injuries of the heart of which examples of both right-sided and left-sided injuries are given, Powell mentions cardiac failure from overtaxation. There are two factors always at work in different proportions in different cases in producing cardiac failure from great or prolonged exertion, namely, direct fatigue of the nervo-muscular tissue of the heart and poisoning of the blood of auto-metabolic source. The treatment of acute failure of the heart from over-strain involves a period of a few weeks' complete rest and often many months of careful supervision. Young people make a rapid and generally complete recovery, provided no actual lesion has been produced. In youths and young men a degree of irritability of the heart is often observed for many months, the patient suffering from attacks of palpitation and cardiac pain on slight fatigue or exertion, and often at night. Another form of fatigue heart failure is that frequently met with in acute diseases as in pneumonia, enteric fever, acute bronchitis, in old people during a severe paroxysm of asthma, and in other conditions, such as functional disturbance from some temporary cause. There are a few factors concerning the treatment of heart failure in acute disease which should be looked for as indications. They are: 1. Maloxygenated and otherwise contaminated blood supply to the heart muscle and nerve. 2. Excessive weight of blood burdening the heart. 3. Exhausted innervation from sleeplessness and physical cardiac failure. 4. Positive obstruction to the flow of the blood from the lungs. 5. Changes in the texture of the heart muscle incidental to the disease, and especially to the pyrexia. Speaking of angina, the lecturer believes that in the larger class of cases it is a functional disease, a cardio-vascular neurosis. In many cases it is dependent upon disorderly action of the vasomotor nerves, and is associated with a sound heart. In any other cases we have a similar mechanism, but with an unsound heart-aortic regurgitation, aneurysm, senile fibro-fatty hypertrophy, uremic heart and coronary disease. He also mentions **plethora** as a cause of a cardiac failure as well as the influence of

tobacco and epilepsy. Powell closes his lecture with reference to the condition of "**cardiac hesitation**" with pulse of uneven rhythm not amounting to intermittency, and presenting occasional attacks of fainting. This condition is not unfrequently present among anemic children, especially young boys between the ages of six and puberty. A distinction between this form of heart failure and *petit mal* is often difficult, and he is strongly inclined to regard the two conditions as allied. [T. L. C.]

2.—Lewis C. Bruce contributes a paper on clinical and experimental observations upon general paralysis of the insane. He defines the condition as a disease marked by progressive degeneration of all the bodily and mental functions, commencing first with those most highly developed and recently acquired, and ending with complete wreckage of mind and body. The disease is regarded as incurable, but remissions which often simulate recovery are by no means uncommon. The typical disease is further peculiar in having several stages. In the first stage the patient is often acutely ill with pyrexia, loss of body weight, restlessness and stages of excitement. In the second period the patient becomes fat, facile, lazy and liable to congestive seizures. In the third stage the patient again loses weight, becomes demented and physically paralysed. This writer has made a number of observations upon patients suffering from undoubted general paralysis. He divides these observations into: 1. Those observations made upon patients in whom the disease was steadily progressive. 2. Those observations made upon patients in a state of remission. 3. Those concerned in an attempt to produce remission. He divides the condition of the second stage, the state of remission, into those in which the remission follows acute attacks of intercurrent disease, of which class he has seen remission occur after acute erysipelas of the scalp, severe carbuncles, etc. Such remissions are preceded by a high and long-continued hyperleukocytosis. Secondly, he has observed remission occur naturally and without obvious cause during the course of the disease. The temperature in these cases was never febrile, but the outstanding feature was the fact that the number of leukocytes in the early stage of remission, rose higher than they are in ordinary health, varying between 9000 to 12,000 per c. mm. of blood. As the remission became fairly established, the leukocytosis gradually fell to that of ordinary health. The blood serum of such cases contains some antitoxic substance which is not present in patients in whom the disease is progressive nor in the serum of healthy persons. The power of the blood serum to agglutinate B. coli in dilutions varying from 1 to 5 to 1 to 20, was tested in 10 cases in states of remission; 7 gave a definite agglutinative action. His third observation includes those cases in which there have been attempts to produce remission. He believes that the majority of cases of general paralysis is due to toxic poisoning, the toxins being bacterial toxins absorbed through the stomach or intestines. He accounts for the febrile attack by stating that it is probably due to the actual entrance of bacteria into the blood tissues of the patients, and that during periods of remission the blood must possess some antitoxic substance. His conclusions are of interest. He states that: (1) General paralysis is a disease directly due to poisoning by the toxins of bacteria whose point of attack is through the gastric and intestinal mucous membrane. 2. The poisoning is probably a mixed poisoning, but B. coli is apparently one of the noxious organisms. 3. The result of treatment with serum taken from a case of general paralysis in a condition of remission and injected subcutaneously into an early progressive case points strongly to the fact that some form of serum treatment is the proper treatment for this as yet incurable disease. [T. L. C.]

3.—W. Ford Robertson presents some observations bearing upon the question of the pathogenesis of general paralysis of the insane. There is now practically no dispute as to the fact of the toxic origin of the disease. Nearly all

authorities recognize that antecedent syphilis is the essential cause in a very large proportion of cases. An endeavor has been made to discover some indirect relationship between the original toxic agent and the morbid process which occurs in the nervous system. The theory of the premature involution of the cortical nerve cells is advocated especially by Mott and Krafft-Ebing. In general paralysis there exists a primary progressive decay of the nerve cell which ontogenetically and phylogenetically may be looked upon as a regressive metamorphosis, a degenerative process which starts in the highest and latest phylogenetically developed structures, e. g., the centers of verbal and written speech; the molecular layer with the tangential system of fibres and the association system of the frontal and parietal lobes. This premature decay according to Mott is progressive and cumulative, and it causes phenomena of irritation, manifested by mental and physical symptoms. Robertson approaches the study of the condition by the discussion of this theory of premature involution of the cortical nerve cells, then discusses the theory of chronic toxemia, the source of the toxins, and the state of the gastro-intestinal tract in general paralysis. This writer does not believe that the gastro-intestinal lesions found in such cases are significant etiologically. He concludes with Dr. Bruce that general paralysis depends upon the condition of gastro-intestinal autointoxication which results from excessive growth of the micro-organisms which normally inhabit the alimentary tract. He would exclude the mention of any single form of micro-organism. He states that there is reason to believe, however, that certain forms obtain an ascendancy, especially some belonging to the "colon group." General paralysis is dependent upon the occurrence of chronic toxemia of gastro-intestinal origin. The toxins are mainly bacteria and are formed in consequence of a partial breakdown of those forces by which the harmful development of the micro-organisms that constitute the ordinary flora of the alimentary tract is normally prevented. The toxins are absorbed and tend specially to produce proliferative and degenerative changes in the vessels of the central nervous system. These vascular changes tend to set in earliest in those parts of the brain that are relatively best supplied with blood, because their walls are brought in contact with the largest quantity of toxins. *Tabes dorsalis* is dependent upon the same form of toxemia. The part played by syphilis in the pathogenesis of general paralysis and *tabes dorsalis* is essentially that of altering the natural immunity. There is some evidence in favor of the hypothesis that this alteration in the natural immunity is dependent upon commencing exhaustion of the leukoblastic function of the bone marrow. The treatment of general paralysis and *tabes dorsalis* should be directed primarily to the correction of the disorder of the alimentary tract. Probably the only means by which it will be found possible to check the excessive growth of the gastro-intestinal bacteria is that of the employment of specific antitoxins. To arrest the disease by such means may be more practicable than would at first sight appear, because it is probable that the specially injurious toxins are the products of only a few bacterial forms. [T. L. C.]

4.—Halliburton and McKendrick present a report on the experimental inquiry into the pathology of gastric tetany. Gastric tetany is that tetany observed with dilatation of the stomach. A case is reported of a man about middle life who for fully 15 years had had more or less stomach disorder. Within the last few years there was severe pain after taking food, and this was relieved by the vomiting of a large quantity of sour smelling material. Hydrochloric acid was seldom present in excess. On one examination it was absent, but it was generally normal in amount. Sarcinae were usually present. He had had gastric ulcer when a young man. For the last three years he has used a stomach tube two to three times a day. There was a sudden onset of a state in which the patient was semi-conscious, but soon passed into a state of coma which

lasted for 36 hours. By the use of drastic medicines and injections high up into the bowel an evacuation was obtained which quickly caused the nerve symptoms to abate. The hands and fingers were in a state of contracture, forming the usual and characteristic "accoucheur's hand." The hands were equally affected on the two sides, but the feet were free. There were no spasms of the hands and fingers but a long continued contracture which lasted during the whole period of unconsciousness. After the contracture abated the cardinal signs of Erb, Trousseau, and Chvostek could not be elicited. The stomach was markedly dilated, and the peristaltic wave was readily obtained. The urine during the tetanoid seizure contained a trace of albumin and also acetone. After the cessation of the spasm, these substances disappeared and gave place to a trace of sugar. The specific gravity averaged 1028. The vomit contained acetone, hydrochloric, acetic and butyric acids, but no sarcinae. An operation was performed after the patient had recovered sufficiently, and in a few months his condition was satisfactory in every respect. Mayo Robson has shown that immediate operation of the nature of a pylorectomy or gastro-enterostomy will relieve the symptoms and prevent the recurrence of this grave disorder. This treatment prevents the retention of the food in the stomach, and the consequent absorption into the blood of toxic products. The contents of the stomach from this case of gastric tetany were emptied into a beaker and to them was added six times their amount of rectified spirit. The mixture was allowed to stand 24 hours, then filtered; the filtrate was evaporated on a water bath to dryness. The residue was taken up with alcohol, filtered, and the filtrate a second time evaporated to dryness. This process was repeated twice. After filtration the solution was used for injection experiments. The original tetany fluid had a strong chloroform smell and was extremely acid, and the substance or substances which were investigated were odorless and soluble both in alcohol and physiological salt solution. Five experiments were undertaken upon animals. These authors have found as a result of their experiments that a toxic substance existed in the stomach, which when injected into an animal produced a fall of blood pressure and slowing of the heart beat. This was not present in the normal gastric contents of health. After neutralization of the tetany fluid practically no fall of blood pressure was obtained. They were unable to determine the nature of this substance; it has a marked acid reaction. By its injection into animals it causes either direct or reflex excitation of the cardio-inhibitory center. It is therefore, by no means improbable that other centers in the brain or cord are excited similarly. The gastric contents were obtained after the patient was in a state of partial convalescence, and it is possible, had the fluid been obtained during the period of coma with contracture, this poisonous substance would have been present in a larger amount and would have produced convulsions and death.

[T. L. C.]

5.—Hamilton Wright has studied the changes in the neuronal centers in the neuritis accompanying *beri-beri*. He believes that the neuritis of *beri-beri* is not radically different from other parenchymatous neuritis and that the various parts of each neuron are interdependent, disturbance or destruction of the axonal prolongation resulting in disturbance or destruction of the nutritional center and the poison of *beri-beri* probably works so forcibly on the neuron that its stability is wrecked, and the whole structure soon destroyed. Recovery is impossible from the first. One has only to see a strong coolie enter the hospital with a slight edema, weakness of muscles, and sensory disturbance to observe the rapid progress of the paralysis and wasting of the limbs and often of the diaphragm, with sudden death from respiratory or heart failure, in spite of all symptomatic treatment, to feel that only a specific will be of use in such cases. The dislocation of the nuclei and slight breakdown of the chromophilic granules in the cells

of all these cases is probably a pseudo-degeneration, and the cause, so far as the afferent side of the nervous system is concerned, of the hyperesthesia, paresthesia and algosia constantly observed in this and other forms of peripheral neuritis. This investigator suggests that the atrophy of the fibres probably accounts for the total and partial anaesthesia, and the changes in the cells by modifying the incoming impulses. The important point here, however, is that in the neuritis of beriberi there is more or less change in the bodies from which the atrophied nerve fibres take origin. This is true of both spinal and bulbar neurons.

[T. L. C.]

6. Samuel Sloan discusses *faradisation of the head in the treatment of chronic insomnia and associated neuroses*. In 46 cases of disordered cerebral function the neurosis associated with the insomnia was the common type of nervousness, with headache, lightness of the head, bad dreams, night startings, a feeling of confusion when adding up figures, a feeling of thickness in the head, creepy feelings in the head, etc., while in nearly every one of the cases the primary complaint was loss of sleep or imperfect and unrefreshing sleep. He has observed cure in 45.5 per cent. of cases; marked improvement in 32.5 per cent.; some improvement in 11 per cent.; no appreciable result in 9 per cent.; cases which seemed temporarily worse, 2 per cent. He believes that the real influence of the treatment arises from the restful action induced in each molecule of the brain substance by the gentle rhythmic impulses of the current, reckoning these at over 100,000 during each sitting, and resembling the cerebration following change of scene and of occupation. Essential to this treatment is an instrument for measuring the amount of current employed. For this purpose he has been lately using the newest form of his faradimeter. The maximum amount of current given is one milliamperé. The dose at the first sitting should not exceed 1-3 of a milliamperé. Not only must the secondary current be controlled by a powerful rheostat, but the battery current to the primary should also have a rheostat controlling it, say of 50 ohms. The electrodes are soft and are applied to the brow and nape of the neck. The vibrations of the rheotome should be the fastest attainable. The current should be applied for 15 minutes each time; three times a week for two weeks, or twice a week for three weeks. Six applications in ordinary cases generally prove sufficient. [T. L. C.]

7.—James H. Mortabet discussing *mal de mer* believes that in cases of severe retching and persistent sea-sickness, nothing is so trust-worthy as a hypodermic injection of morphine. He advises those who suffer from sea-sickness to provide themselves with a good flannel roller bandage 12 feet long and six inches wide, and wind it around their trunk over the whole width of the abdominal region. This will frequently afford great comfort by preventing the contents of the viscera from undue movement. A few turns of a surgical bandage around the head also appear to allay a good deal of the accompanying headache. [T. L. C.]

2.—Will be abstracted when the lectures are completed. [F. J. K.]

3.—H. Littlewood describes a method of performing *gastro-intestinal and intestinal anastomoses* without the use of any mechanical contrivance. After selecting the portion of bowel to be approximated the forceps of Boyen, the blades of which are covered by rubber tubing, is applied and the bowel incised or resected as the case may be. A considerable portion of the presenting mucous membrane is then excised before being sutured. This excision of the mucous membrane permits a wider approximation of the other coats of the intestine. Catgut is used as the suture material. The author has employed this method of resecting the mucous membrane in a number of cases and has found it very satisfactory. [J. H. G.]

4.—Macnaughton-Jones records an interesting case of *ectopic gestation* in which a *septic infection of the gestation-sac* occurred. Operation was performed but despite every means employed, including enemata, saline injections, and washing out of the stomach, death occurred on the seventh day after operation. The temperature never exceeded 102 degrees F., and there was an absence of the usual symptoms of general peritonitis. It would seem that the source of infection must have been through the adherent bowel. The patient having suffered from retroversion of the uterus, the early symptoms might easily have lead to the impression that it was enlarged retroverted and gravid uterus. [W. A. N. D.]

5.—White believes that many of the cases diagnosed as *gastric ulcer, occurring in women*, are instances of some other undescribed malady. He maintains that this undescribed condition occurs almost exclusively, if not only, in women, usually between the ages of 20 and 40. He also states that this disease is in some way associated with chlorosis, and that its chief symptoms are gastric pain, nausea, vomiting, and hematemesis. The patient does not lose weight, and such complications as pyloric stenosis, adhesions, and subphrenic abscesses do not occur. He emphasizes that the differential diagnosis between this condition and gastric ulcer is indeed very difficult. The prognosis of this affection is good, although relapses are frequent; death may occur from hemorrhage, and upon the post-mortem table no cause for it is found. From the standpoint of operative treatment, he calls attention to the importance of separating gastric ulcer proper from this condition, for the surgeon can do nothing to control the hemorrhage which occurs in the undescribed affection, and further, that some patients have died after operation; this condition in itself being rarely fatal. [F. J. K.]

6.—F. B. Judge-Baldwin reports a case in which a five year old boy inspired a portion of beech nut. Examination of the larynx a short time afterwards showed a nearly complete bilateral palsy of the adductors. Auscultation revealed trouble in the left lung. The patient suffered so much difficulty in respiration that on the second day after the accident tracheotomy was performed. A week after the operation portions of the nut were found on the dressing over the tracheal opening. The patient made a satisfactory recovery. [J. H. G.]

7.—Simpson, in recording 3 cases of *puerperal eclampsia*, remarks that whether urea is the actual excitant of the nerve-centers or whether the excitant is a product of decomposition derived from urea, has not been satisfactorily explained, but the uremic theory finds the largest amount of support. The accumulation of the toxins in the blood is due to the faulty elimination by the kidneys of the urea or waste-products of tissue metabolism, which are much increased in the pregnant state. In nephritis these waste-

products accumulate rapidly, but pressure also contributes largely, and it is most in primiparous cases, where pressure and tension are greatest, that eclampsia occurs. According to statistics 60% of the cases of eclampsia occur in primiparae. Constipation, which is the rule in pregnancy, contributes in a great measure to this pathological condition. The author believes that 10% is about the normal mortality of this disease. As regards treatment, he advocates the simpler methods, first—diuretics, diaphoretics, bromide, chloral, and chloroform—before resorting to morphine or hypodermoclysis, keeping in mind the safety of the patient above all other things, and the particular treatment as of secondary importance. Venesection is a valuable form of treatment if the patient is plethoric, but to bleed indiscriminately is bad treatment. [W. A. N. D.]

MEDICAL RECORD.

July 13, 1901.

1. Hydrophobia and the Pasteur-Methods. CHARLES WINSLOW DULLES.
2. The Etiology of Alopecia. DELOS L. PARKER.
3. The Future Treatment of Hay Fever. H. HOLBROOK CURTIS.
4. The Present Status of the Carcinoma Question. N. SENN.

1.—Dulles writes upon **hydrophobia and the Pasteur methods**. The author gives a review of some of the literature pertaining to this disease, and embodies in the article ample evidence to show that after a careful examination of statistics of every country where Pasteur Institutes have been established, the mortality from hydrophobia has actually increased. He strongly recommends the enactment of a dog-muzzling law, as the most important measure for limiting the ravages of this disorder. [T. L. C.]

2.—Parker discusses the **etiology of alopecia**, and after considering practical, as well as experimental evidence, he advances the theory, that it is **not unreasonable to suppose that this condition is due to auto-infection**. The poison, which he calls trichotoxin, is absorbed by the blood from the air vesicles of the lungs. He further states that this poison is elaborated during decomposition of organic matter normally present in respired air. [T. L. C.]

3.—Curtis, after a careful consideration of all sources, from which he has obtained information including his own personal experiences, believes that the future treatment of cases of hay fever, dependent entirely upon rag weed as the exciting cause, will be found in the immunizing plan. Curtis recommends giving from 2 to 10 drops of the tincture or fluid extract of ambrosia artemisiae, in water, three times a day, during the two weeks preceding the time at which the paroxysm is expected. When there exists a mixed infection, and when the cases show a preponderance of asthmatic symptoms, a nasal spray of suprenal extract may be employed with benefit. [T. L. C.]

4.—Nicholas Senn discusses the present status of the carcinoma question under the head of 27 propositions. These include the statement that the direct medication of carcinomatous tissue by parenchymatous injections has no influence in retarding and arresting its growth, while the injection of sclerogenic substances into connective tissue around the border of the tumor appears to restrain the local extension of the disease by impairing the blood supply to the parenchyma of the tumor. Local applications to ulcerating carcinomata must be considered at best in the light of palliative measures. The early and radical operative treatment offers the only prospect for permanently eliminating the disease. The increase of carcinoma, seemingly shown by some recent statistics, is more apparent than real. Heredity is recognized a potent cause of carcinoma. A careful study of the experimental researches and bacteriological and histological investigation concerning the etiology of carcinoma does not at the present time warrant us to claim for this disease a parasitic origin. The positive results of implantation and inoculation experiments have so far failed in establishing beyond all doubt, upon a bacteriological and histological basis, the parasitic cause of carcinoma. [T. L. C.]

NEW YORK MEDICAL JOURNAL.

July 13, 1901. (Vol. LXXIV, No. 2.)

1. The Home Treatment of Pulmonary Tuberculosis. ROBERT H. BABCOCK.
2. Antitoxin and Intubation in the Treatment of Laryngeal Diphtheria, with a Summary of 230 Operations. BURT RUSSELL SHURLY.
3. The Influence of Mouth-breathing Upon the Dental Arch. M. D. LEDERMAN.
4. A Leaf from the Ancient History of the Anatomy of Catarrh. JONATHAN WRIGHT.
5. Address in Pathology, delivered at the Meeting of the Texas State Medical Association, in Galveston, April 26, 1901. ALLEN J. SMITH.
6. Neuroses as seen in Orthopedic Practice. B. E. M'KENZIE.
7. Sexual Intemperance; Some Explanation of What is Meant by the Term. JENNIE G. DRENNAN.
8. An Operation for Prominence of the Auricle. THOMAS R. POOLEY.

1.—R. H. Babcock gives the following points in the **Home Treatment of Pulmonary Tuberculosis**: (1) The most successful treatment of the disease is hygienic and not medicinal. (2) This includes (a) the building up of tissue resistance by superalimentation; (b) a continuous, or as nearly continuous as possible, sojourn in the open air under conditions that are determined by the patient's temperature; (c) hydrotherapy; (d) the careful and methodical regulation of the patient's daily life. (3) Although these requirements can be best secured in a sanatorium, they can be obtained at the patient's home regardless of climatic conditions there prevailing. [T. M. T.]

2.—B. R. Shurly gives three varieties of pseudomembranous invasion of the larynx: (1) True laryngeal diphtheria, usually caused by the Klebs-Loeffler bacillus primarily invading the larynx; (2) A pseudomembranous inflammation following a nasal, tonsillar or pharyngeal exudate, most frequently of the Klebs-Loeffler variety; (3) A pseudomembranous laryngitis secondary to the common infectious diseases of childhood, such as measles, scarlet fever, etc. The predisposing causes that influence the development of the Klebs-Loeffler infection are (1) A lowered resistance from the presence of adenoids and hypertrophied tonsils; (2) Age. Children between the age of one and six years are more susceptible. The administration of antitoxin should be made in every doubtful case of tonsillar exudate in children between one and eight years old. [T. M. T.]

3.—The **Influence of Mouth-breathing upon the Dental Arch** has been studied quite extensively by M. D. Lederman, who gives the following definite conclusions: (1) That the alveolar arch of the newborn is characterized by its shortness. Furthermore, it gradually assumes a higher and broader aspect in proportion to the growth of the adjacent structures; (2) That in subjects where adenoid vegetations exist, the arch is found to be distinctly higher, longer, and narrower than the normal one; (3) That the configuration of the palate is not dependent upon the skull formation; (4) That anomalies of malposition of the teeth are very frequent in abnormal conditions of the maxillary bone and alveolar process. [T. M. T.]

MEDICAL NEWS.

6. Empyema. JOHN A. HARTWELL.
7. Sexual Neurasthenia in the Male; A Plea for a More Accurate Use of the Term; Treatment of the True Form with Citation of Cases. RAMON GUTERAS.
8. Masturbational Neuroses. WILLIAM C. KRAUS.

1.—T. M. Rotch gives the following group of **Diseases of Nutrition in Infants**: (1) Infantile atrophy; (2) Infantile scorbutus; (3) Rhachitis; (4) Osteomalacia. The first two diseases will be found occurring during the first two years of life, while osteomalacia, unlike the other three diseases; only occasionally occurs in children and is more a disease of adults. It, however, at times so closely resembles rhachitis in its manifestation that it should be included in the group, but it is not a disease characteristic of infancy as is the case with the others. He states that the etiology of the whole group is obscure, but classified under one head, clearly presents a picture of a vice of nutrition. Rotch emphasizes the importance of these diseases, and believes that the whole group would be eradicated if more care were used in the preparation of the food for infants and less medicinal treatment used. [T. M. T.]

6.—J. A. Hartwell sums up his article on **empyema** as follows: (1) Children are especially liable to empyema following pneumonia; (2) Pneumonia caused empyema in 50% of the cases considered in his article, and such cases were of severe type; (3) Tuberculous family history exerts little influence on empyema; (4) In about one-sixth of the cases the empyema was sacculated; (5) The pneumococcus was found in 50% of the cases where examination was made; the streptococcus in 33.13%; the staphylococcus in 8%; the tubercle bacillus in 4%; and no bacterium in 16%. The pneumococcus produced the most virulent infection; (6) Chloroform was the anesthetic of preference. Deep narcosis is contra-indicated, owing to the danger of pus being drawn into the other lung from a ruptured bronchus; (7) In adults with general empyema two inches of the seventh and eighth or eighth and ninth ribs in the posterior axillary line should be resected. In children the same length of the seventh rib. Simple incision, with our present knowledge, is rarely advisable; (8) Operation is indicated as soon as diagnosis is made; (9) Irrigation of the abscess cavity with bi-chloride solution, 1-5000, or carbolic acid, 1-100, is indicated, unless drainage is perfect and no sepsis is present. In children the solutions may be weaker; (10) The mortality from the empyema proper was 15%. We may hope to reduce it to one-half that number by earlier and more radical treatment. [T. M. T.]

7.—R. Guteras defines **Neurasthenia** as a chronic, functional, nervous disorder which is characterized by an excessive weakness and irritability of the nerve centers so that the patient is exhausted and reacts immoderately to slight irritation. He differentiates sexual neurasthenia from the others only in the multififormity of its symptoms in their relatively greater severity and in the fact that the chief source of trouble, whether recognized by the patient or not, lies in some part of the genital tract. In a great many cases nothing is found the matter with the genital tract other than a stricture of a patch of granular tissue, or a denuded area of the urethra, and it is advised that thorough examination of the genital tract should be made in every case, as a general practice before attempting any line of treatment. [T. M. T.]

8.—W. C. Kraus warns against giving favorable prognosis in cases of functional nervous diseases with an underlying history of masturbation coupled with a neurotic family history. Cases giving no history of masturbation which fail to respond to treatment after a sufficient interval, should be most rigidly interrogated, and in many cases the suspicion of masturbation will be verified. It is almost useless to try any form of treatment or to expect to obtain any definite results in the functional neuroses if this habit is not discovered and corrected. If, then, this habit is so widespread among the young; if it tends in suitable cases to undermine the physical and psychical forces; if it renders its devotees almost

impregnable to rational scientific treatment, is it not a practice which should be discouraged rather than encouraged, defeated rather than surfeited? The author states that he would rather treat any form of nervous diseases than a case of masturbational neurosis. [T. M. T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

July 11, 1901.

1. Two Cases of Pregnancy Complicated by Mitral Insufficiency. HENRY D. CHADWICK.
2. Albuminuric Retinitis and Uremic Amaurosis, with Especial Reference to Their Occurrence in Pregnancy. EDMUND W. CLAP.
3. Congenital Pelvic Malposition of Left Kidney in a Woman. JOHN W. DEWIS.

1.—Henry D. Chadwick reports two cases of pregnancy complicated by mitral insufficiency. Both patients died. In the first case, death occurred 21 days after delivery. The baby lived and was a strong, healthy child. The second patient died 10 days after delivery of a still born fetus. The author, discussing these two cases in detail, believes that such patients should be watched closely from the beginning and when lack of compensation is shown by pulmonary congestion, it is not only justifiable, but one's duty to advise and urge upon the patient the necessity of terminating the pregnancy as speedily as possible. [T. L. C.]

2.—Clap, in a paper entitled, **Albuminuric Retinitis and Uremic Amaurosis, with Especial Reference to Their Occurrence in Pregnancy**, states that both albuminuric retinitis and uremic amaurosis are rare conditions in pregnancy, but very important when they do occur. "Albuminuric retinitis is a disease accompanied by immediate visible changes in the eyes. Albumin is always present in the urine. It may occur at any time during pregnancy, especially beginning during the first two months or after the sixth month. Its prominent symptom is gradual failure of vision. It is very apt to recur in successive pregnancies, though not necessarily. Blindness is almost never caused by the first attack, but more and more damage is done by each recurrence. Uremic amaurosis is a disorder of the visual apparatus not accompanied by immediate visible signs in the retina, although it may finally lead to atrophy. It occurs late in pregnancy, usually with other signs and symptoms of eclampsia, so that it seldom has to be considered alone. It apparently never destroys vision by the first attack. Like albuminuric retinitis, it is very apt to recur in subsequent pregnancies. The treatment of both conditions is the treatment of the albuminuria and nonuse of the eyes, enforced by atropine and dark glasses, if necessary. The prognosis of uremic amaurosis as to sight is favorable for the first attack, and less and less so for each succeeding attack; but the importance of this is usually overshadowed by the uremic condition present. The prognosis of albuminuric retinitis as to sight is favorable for the first attack, if occurring after the sixth month, but grows worse if it occurs in succeeding pregnancies. Prognosis for sight is bad if it comes on earlier than the sixth month, especially if it begins during the first two months; and in these cases great danger to both child and mother may be expected from eclampsia. As to abortion or premature labor, we are seldom called on to consider it for the preservation of sight alone, since so many and such grave dangers are present to both mother and child from uremia. If we consider the preservation of sight a cause for premature labor, then it may have to be done in uremic amaurosis recurring in successive pregnancies, with progressive loss of sight; the degree of impairment of sight and the amount of damage done to the optic nerve deciding the question. In retinitis albuminurica occurring early, abortion should be considered if the retinitis is of a severe type, especially if hemorrhagic, or if a slight retinitis progresses under treatment, remembering that in these cases the life of the child is uncertain any way, and the mother runs grave risks of eclampsia if the pregnancy goes on to term. In retinitis coming on after the sixth month it is best to wait and watch carefully, especially in a first attack, and not to induce labor unless some other albuminuric symptom demands it. In the subsequent attacks the damage to vision and the severity of the retinitis may turn the

scale in favor of premature delivery, even when slight eclamptic symptoms are present." [M. R. D.]

3.—John W. Lewis reports a case of **congenital pelvic malposition of the left kidney in a woman**. Behind and to the left of the uterus a smooth, firm mass was palpable, somewhat movable with a slight fissure, or notch, in the border. It was not particularly sensitive to touch. The urine was normal. The right kidney could be made out by palpation, but the corresponding locality on the left side seemed thinner, and no kidney could be found. Cello-tomy was performed. The tumor was retroperitoneal, and lay over the promontory of the sacrum, about two-thirds being in the cavity of the pelvis. It was a firm kidney-shaped mass, considerably flattened and imbedded in a soft, thick capsule, and could be moved up and down about two inches. The blood supply could not be detected nor the ureter located. On cutting through about three-eighths inch of the fatty cushion, the kidney cortex was exposed, and the incision again closed with catgut. The patient made an uneventful recovery. As a rule kidneys in malposition are fixed, but in this case there were two inches of movement. Malposition does not interfere with the normal functions of the kidney, although it does predispose to complications. In this patient the kidney lying between the sacrum and uterus, appears to have predisposed the patient to abortion. [T. L. C.]

1.—Anders delivered the annual address before the section on Practice of Medicine at the 52d meeting of the American Medical Association. In this address he outlines the future work of the section and emphasizes particularly the advisability of appointing a special committee on scientific business for this section. He further suggests that such a committee should hold office for a term covering from three to five years, and that the secretary of this section should be a member of such a committee, and the chairman a member ex-officio. One month prior to the annual meeting all papers intended for presentation should be handed in and scrutinized by the committee. Anders makes a plea for closer and more intimate relations between the medical man and the surgeon. [F. J. K.]

2.—John B. Deaver considers that the **appendix is the most vulnerable of the abdominal organs** because of its delicate blood, nerve, and lymphatic supply, its length and calibre, and because of its liability to traumatism in its association with the psoas muscle. It is shown that it is very difficult and oftentimes impossible to clinically distinguish the different pathological varieties of appendicitis. The majority of cases of appendicitis are of a chronic nature. Many cases diagnosticated acute appendicitis are only exacerbations of chronic inflammation. Not infrequently the whole pathology of appendicitis is demonstrated in one patient. Deaver thinks that obliteration of the lumen of the appendix is of the rarest occurrence, not to be expected, and never to be relied upon. Particular stress is laid upon the rapidity and suddenness with which the appendix may become diseased and gangrenous, giving rise to a fatal peritonitis. The three principal symptoms of appendicitis are pain, tenderness, and

rigidity, and of these pain is much more important. The pain is paroxysmal and may at intervals almost disappear. The site of the pain will entirely depend upon the position of the appendix. In examination of an abdomen for appendicitis always palpate at a point some distance from the supposed seat of disease and then gradually approach the point of tenderness. An abrupt cessation of pain indicates gangrene of the appendix. Both temperature and blood count are considered of little value in making a diagnosis. As soon as a diagnosis of appendicitis is made the appendix should be removed. [J. H. G.]

3.—Talbot read a paper entitled, "**Preliminary Work**," before the section on Stomatology. The author examined 1958 teeth, removing 1017 pulps. These teeth were obtained last winter from the Chicago Dental Surgeons. The technique of removing the pulp consisted in cracking open the teeth; they were then placed into Miller's fluid and a 1% formalin solution. The pulp was lifted out of its chamber, as far as the apex, in nearly every case. In every instance it was found necessary to crush the root of the tooth in order to detach the pulp. From the macroscopical examination he divides the pulps into a number of varieties. He emphasizes that pulps, which were removed from teeth immediately after extraction, were not found adherent to the walls of the canals, and he therefore concludes that it seems evident, from a macroscopical standpoint, that nerve fibres do not enter the dentine. 11.9% of the 1017 pulps collected were found more or less mummified. The teeth that contained mummified pulps were dense and quite difficult to crack. In those possessing partially mummified pulps there was a line of demarcation between the part filled with blood and the dried end. Adhesions existed between the dried portion and the end of the root. In some instances all of the pulps of the teeth removed from the same individual were mummified. Obliteration of the pulp was observed in abraded teeth. He found 1.5% of calcified and calcareous pulps, and 1 instance of fungoid pulps. 11.1% of the pulps were exposed and infected with pus micro-organisms. In some instances inflammation extended throughout the entire pulp. [F. J. K.]

4.—Latham discusses the literature pertaining to the pulp. [F. J. K.]

5.—Anderson gives an account of the methods employed in the preparation of teeth for histological study. He divides the methods into (1) the hard or ground methods; (2) injection methods; (3) structural methods. The latter are divided into those used to demonstrate cellular structures, and those used to demonstrate nervous tissues. [F. J. K.]

7.—Steeves discusses the importance of recognizing the methods by which infectious diseases are conveyed from one patient to another by means of instruments or otherwise, and the character of the infection itself. Syphilis is the most common infection which is carried from the mouth of one patient to that of another. He suggests the probability of conveying the germs of scarlet fever and diphtheria from one patient to another by unclean instruments. The bacillus of diphtheria has been found in tooth cavities. The author states that the bacillus of tuberculosis could be conveyed from the mouth of a tuberculous patient on dental instruments, and deposited into the mouth of another person. [F. J. K.]

8.—M. L. Heidingsfeld discusses the **treatment of cutaneous cancer** showing that because of the indifference of many medical men to this condition, and because of fear of the knife, patients suffering from skin cancer find themselves in the hands of the cancer quack. The methods of these quacks and illustrations showing the results of their work are presented. The author has used with great satisfaction an arsenic paste composed of 5 parts each of arsenous acid and pulverized gum arabic and 2 parts each of cocain and glycerin with sufficient water to make a paste. The cases in which he has employed this method have not

yet stood the test of time but the immediate results have proved very pleasing. The paste is applied upon cloth and is allowed to remain from 12 to 36 hours according to the amount of inflammation which it produces. [J. H. G.]

9.—Anthony writes upon the relationship of syphilis to blastomycetic dermatitis. The author carefully weighs the evidence that supports the view that this condition belongs to the class of vegetating syphilids. He also states the reasons for separating this disease from syphilis. He contends that before any conclusions can be arrived at a more careful and thorough study must be made of blastomycetes occurring in cases of surgical tuberculosis. [F. J. K.]

11.—Itavogli reports a case of erythroderma squamosum occurring in a boy, three years old. This patient had three attacks of this skin disease. The last attack occurred on March 5, 1901, when the skin of the entire body, excepting the palms of the hands and the soles of the feet, were red and covered with scales, that varied in size and appearance in different anatomical regions. The blood examination revealed 5,400,000 erythrocytes per cubic millimeter, and 8,400 leukocytes per cubic millimeter. The differential count was made with the following result: small lymphocytes 23%; large lymphocytes, 2.1%; polymuclear leukocytes, 73%; eosinophiles, 1.4%. The patient did not complain of itching of the skin, or of stomach or bowel disturbances, and during the entire course of the illness there was no fever. The urine was apparently normal. The condition yielded readily to treatment consisting of anointing the body with cod liver oil. [F. J. K.]

AMERICAN MEDICINE.

July 13, 1901.

1. Removal of the Female Urinary Bladder for Malignant Diseases. MATTHEW D. MANN.
2. Total Extirpation of the Urinary Bladder. J. WESLEY BOVEE.
3. Ankylostomiasis in the United States. Report of a Case. HERMAN B. ALLYN and M. BEHREND.
4. Phlebitis Following Abdominal Operations. ALBERT VANDEVEER.
5. Report of a Case of Carcinoma at the Cardiac End of the Esophagus, Etc. C. D. SPIVAK.
6. Impoverished Blood and Its Relation to Insanity. J. W. WHERRY.
7. A Medico-Surgical Bedstead. ADOLFO LURIA.

1.—Mann discusses the operation for the removal of the female urinary bladder from malignant disease. An account is given of the frequency of carcinoma of the bladder, and reference is had to the statistics bearing upon this point. The author also gives a brief account of the pathology and the diagnosis of malignant disease of the bladder. The reports of two cases of removal of the bladder are included in his article. Mann concludes that total extirpation of the urinary bladder for malignant disease is a justifiable operation. To the experienced abdominal surgeon the operation offers no great difficulties, and the patient is given a fair chance for a comfortable continued existence. [T. L. C.]

2.—Bovee discusses total extirpation of the urinary bladder from the standpoint of the history of the procedure, the methods and results of operations, and finally draws the following conclusions: It is not advisable to perform cystectomy for conditions, other than exstrophy, when partial extirpation of the organ is possible, until a more satisfactory means of disposal of the ureters is found. To avoid infection, as far as possible, a small portion of the bladder into which the ureters may be debouched, should be kept intact. The Maydl and the Pozzi operations seem most satisfactory for exstrophy, although the danger of infection is not obviated. Grafting of the ureter into the skin or into the rectum is highly dangerous. Ureterovaginoscopy does not offer perfect results, but practically eliminates ascending infection. The urethral grafting of the ureter does not lessen the constant dribbling of the urine, but seems free from infection. The Mauchaire-Gersuny operation should receive further application, inasmuch as it provides for a sphinctered bladder

and bowel. The author appends a table of 100 extirpations of the urinary bladder. [T. L. C.]

3.—Allyn and Behrend report a case of ankylostomiasis which occurred in an Italian boy, 15 years of age. The patient was admitted to the Philadelphia Hospital on May 28, 1901, complaining of great weakness and pain in the epigastrium. The patient arrived in this country on March 26th, and soon after began to feel ill. On admission he complained chiefly of headache, epigastric pains, muscular pains and weakness, and constipation. He appeared well nourished and the legs were slightly edematous. Upon examination of the heart a loud systolic murmur was heard over the precordial region and over the cervical vessels. Upon examination of the feces numerous eggs of the ankylostoma duodenale were found and also some of the adult worms. A blood examination on May 28th showed: Erythrocytes, 1,220,000 per cu. mm.; leukocytes, 8,650 per cu. mm.; hemoglobin, 15%. Differential count of the leukocytes: Polynuclear cells, 71%; small lymphocytes, 21%; large lymphocytes, 9%; eosinophiles, 1.3%. On June 4th a second blood count was made, which showed that the red blood cells had decreased to 871,875 per cu. mm., while on June 15th the red cells numbered 1,062,500. For a while the temperature ranged between 100°F. and 102°F. The patient steadily improved after admission to the hospital. The number of red blood cells and the percentage of hemoglobin increased. He is still passing ova. The authors state that a later report will be made. [T. L. C.]

4.—Vandever read a paper before the American Surgeons' Association, at Baltimore, on "Phlebitis Following Abdominal Operations, and reported interesting cases. [T. L. C.]

5.—Spivak reported a case of carcinoma of the cardiac end of the esophagus, at the meeting of the American Gastroenterological Association, held at Washington. The points of especial interest in this case were the following: The esophagus was abnormally long, measuring twenty-one inches in length. Insufflation greatly aided in the diagnosis. The patient did not complain of pain in any part of the body, and the appetite was not impaired until three days before death. Only during the last week of the illness the bowel functions were disordered. The breath was offensive during the last two days of the illness. The lower end of the esophagus was not dilated. There was a metastatic involvement of the pylorus. [T. L. C.]

6.—Wherry contends that many cases of insanity are caused by circulatory changes, and that an impoverished condition of the blood is responsible for some of these. In an appended table he gives the averages of blood counts in various forms of insanity. [T. L. C.]

AMERICAN JOURNAL OF MEDICAL SCIENCES.

June, 1901.

1. Cancer Distribution and Statistics in Buffalo for the Period of 1880-1899, with Special Reference to the Parasitic Theory. I. LYON.
2. Chronic Myocarditis and Fatty Degeneration of the Heart. B. ROBINSON.
3. Osseous Cysts of the Tibia. C. BECK.
4. Clinical and Histological Study of a Case of Circumcorneal Hypertrophy of the Conjunctiva. C. OLIVER.
5. Nitrous Oxide and Oxygen as a Surgical Anesthetic. S. GOLDEN.
6. Croupous Pneumonia. G. NORRIS.
7. Heart and Circulation in the Feeble-Minded. J. M. TAYLOR and F. S. PEARCE.

1.—Lyon has made careful studies of the distribution of cancer in the city of Buffalo during the years 1880-1899, inclusive. He has paid particular attention first, to the region of distribution, and second, to the racial distribution. Altogether there were 2113 cases, of which 2005 could be used for statistical purposes. He calls attention to the interesting study of Hebra in the town of Leekau in which the conclusion was reached that cancer infection was probably conveyed by vegetables eaten raw, that had been contaminated by the water of a ditch that ran through certain districts of the town. He concludes that of all nationalities the Irish are the most susceptible to carcinoma. That,

however, a map of the city shows a marked concentration of the disease in the wards inhabited by Germans, and that the Germans and Poles considered together, are distinguished from all other classes by the very high rate of involvement of the stomach, this disease being 10 times more frequent among them than among the native born. In general, about twice as many females are affected as males, but this is not true of the Germans. The disease is increasing, and the proportion of males affected by cancer is greater. The number of cases per hundred thousand of population has increased from 32 to 53. This appears to be largely due to the increased proportion of foreign-born citizens.

2.—Robinson reports some interesting cases in which heart failure occurred in persons who had not previously manifested symptoms of heart disease. In one of these an autopsy was obtained, and atheroma of the coronary arteries was found. He admits that, omitting attacks of acute disturbance, examination of the heart often fails to reveal any signs that are characteristic of myocardial involvement. However, in these cases, very slight exertion will cause distress and perhaps slight cyanosis. He calls attention to the importance of anemia in producing fatty degeneration of the heart, particularly the chlorotic condition that occurs in young girls after acute infectious disease, and the secondary anemia produced by too profuse menstruation. Chronic alcoholism is also a potent factor in those cases in which the process has developed rapidly, or in which a cause exists that can be removed. In young persons there is more likelihood of a cure than in older ones. In pernicious anemia the prognosis is exceedingly grave. The treatment requires the exercise of great judgment. Nauheim baths may be of benefit, or may be detrimental. In some cases one course improves the patient remarkably, and a second makes him very much worse. Iodide of potassium is useful in a variety of conditions. [J. S.]

3.—Beck reports two cases in which cysts developed in the tibia. One, a boy of 10, received a severe injury which was followed by intense pain in the upper portion of the right tibia. Fracture could not be determined. On subsequent occasions he fell on the street and each time was confined to his bed for several weeks as a result of the pain. Swelling developed below the right knee, which, when examined, was found to be painless, and not to involve the knee-joint. Osteosarcoma was suspected, but a Röntgen ray examination showed that the upper portion of the tibia was really paler than the lower part. Incision was therefore performed, and a considerable amount of bloody fluid evacuated, and the cyst closed by crushing its walls inward. The patient made a perfect recovery. Microscopic examination showed the presence of numerous round cells around the blood vessels. The second case, a girl of 13, had received a severe injury 8 months before, followed by swelling of the left ankle. Examination showed enlargement of the lower end of the tibia without involvement of the ankle joint. A skiagram showed the same changes that had been observed in the other case. Incision revealed a large cavity filled with cartilage in the lower end of the bone. This was removed and the patient made a perfect recovery. Beck calls attention to the extreme importance of examining all these cases with Röntgen rays. If this had not been done in the first case amputation would probably have been performed. [J. S.]

4.—Oliver reports a case observed by Dr. J. P. Worrell. A moderately large tumor apparently composed of nodules, pinkish-white in color, had developed in the conjunctiva of the right eye between the cornea and the inner canthus. This was removed, but recurred again, and after excision was thoroughly cauterized. Cauterization was required from time to time as the tumor reappeared. Subsequently a third complete operation was required, and after this the growth did not reappear. Microscopic examination of the growth showed increase in the epithelial structures with marked sclerosis of the surface cells. The diagnosis was hypertrophy of the conjunctiva. [J. S.]

5.—Goldan describes in detail his apparatus for the administration of a mixture of nitrous oxide and oxygen for the purpose of producing anesthesia. As it is difficult to understand this description without the aid of the diagrams, we refer the reader to the original article, in which can also be found the directions for administration. He believes that his method is perfectly safe, producing a mini-

mum amount of shock, and that recovery from the anesthesia is associated with fewer unpleasant symptoms than when any other method is employed. The great objection at present is the expense, on account of the enormous quantities of gas required (100 to 150 gallons of nitrous oxide, and 10 to 30 gallons of oxygen) but when this is a matter of minor importance the advantages are very great. He mentions a number of cases in which anesthesia was maintained for periods varying from 30 minutes to nearly 3 hours. [J. S.]

6.—Norris reports the statistics of cases of pneumonia admitted to the Pennsylvania Hospital since the year 1897. Altogether there were 500. They showed a very marked increase in the disease in latter years, entirely out of proportion to the increase of the city in population. The death rate was 25%; rather more among the Irish and Germans than among the Russian Jews. The negroes are especially susceptible. Among known drunkards the mortality was 67%. It also appears to have been greatest among the aged, and among those exposed to severe outdoor work. The disease was commonest in the months of April and May, and very infrequent from June to September. In 50% of the cases there was chill at the onset. The greatest number terminated on the eighth day, but in 11 cases the disease was prolonged for 20 days or more. In 54 cases there was a pseudo-crisis. Fifty-seven cases gave histories of previous attacks. The great majority of them showed renal complications. Jaundice occurred in 18 cases, of which 11 died. No characteristic changes were noticed in the pupils. The treatment was expectant and symptomatic. Venesection was valuable in the asthenic cases. [J. S.]

7.—Taylor and Pearce report the results of their studies at the Pennsylvania School for Feeble-Minded Children, with special reference to the circulatory and cardiac disturbances. Seventy-two cases among the 955 inmates showed cardiac lesions. Of these there were 40 males and 32 females. In 20 of the males the heart was slightly hypertrophied. In two it appeared diminished in size. In 25 cases the cardiac pulsation was feeble. In 3 cases there was bradycardia. In 6 cases there was a presystolic mitral murmur; in one case, an aortic systolic murmur, in one a double mitral murmur, and in 10 systolic mitral murmurs. In 3 cases there was marked anemia. In 16 cases the pulse rate was over 100. Among the females the heart was hypertrophied in 6 cases, and showed slight displacement in a few others. There were 5 cases of presystolic mitral murmur; one of aortic systolic murmur, and 2 of mitral regurgitation. Irregularity of the pulse occurred in 15 cases. They conclude that the proportion of cases of heart diseases at the school is more than normal, and that, therefore, organic vascular heart disease is a large etiological factor in continuing the downward course of imbeciles. They suggest that careful exercises would be of value. [J. S.]

ARCHIVES OF PEDIATRICS.

June, 1901.

1. Congenital Occlusion of the Duodenum. LOUISE CORDES.
2. Syphilis of the Liver with Large Gummata in Late Childhood. DAVID L. EDSALL.
3. A Report of Two Cases of Cancrum Oris. WILLIAM SEAMAN BAINBRIDGE.
4. Dühring's Disease in Childhood. WILLIAM S. GOTTHEIL.
5. Abscess of the Ethmoid and Antrum of Highmore. J. MORRISON RAY.

1.—Cordes reports a case of congenital occlusion of the duodenum and gives an analysis of 56 other cases from the literature which were diagnosed stenosis and atresia of the duodenum. From an analysis of these cases it is found that total occlusions are more common than stenoses. The cause that may lead to intestinal occlusion are (1) errors of development, (2) volvulus, (3) fetal peritonitis, (4) ulceration, (5) pressure caused by new growths, (6) abnormally long persistence of the omphalomesenteric duct, (7) traction due to inguinal hernia, (8) circulatory anomalies and (9) embolism of the superior mesenteric artery. The

occlusion is most frequently found either just above or just below the orifice of the common bile duct. In the case that the author has had the opportunity of studying personally, a branch of the common bile duct was found opening into the dilated portion of the duodenum above the point of stricture. The child which was of Irish parentage, was born at full term after a normal labor. The baby presented no external abnormalities, except that its face looked old and wrinkled. The child nursed with difficulty and vomited a milk mixture at intervals. The vomitus consisted of a material that resembled bile in appearance and considerable amounts of meconium were passed at intervals. The child was found dead in bed on the fourth day. No evidence of specific disease could be obtained from the child's mother. At autopsy, the duodenum was found to be much dilated and to end blindly just above the papilla of the common bile duct. The walls of this sac, like those of the stomach, were much hypertrophied. The mucosa was smooth and the valvulae conniventes were absent. There was no trace of cicatrization at the point of stricture. Sections of the mucous membrane of the dilated portion of the duodenum showed a normal number and arrangement of the villi and of Lieberkühn's glands. Brunner's glands were found in the submucosa and the peritoneum was normal. [J. M. S.]

2.—Edsall reports the case of a girl, aged 14 years, whose father was strongly addicted to alcohol. There was no history of venereal diseases so far as could be determined in either parent. The child's mother, however, had an opacity of the left cornea, which she stated had existed for many years. The child herself had been an extremely sickly infant, but, according to the mother's statement, had not had snuffles nor skin eruption; nor had she convulsions. The child had been deaf and rather stupid for over 5 years. She complained of swelling of the face, legs and feet which was always worse in the morning, dyspnea, headache and diarrhea. She appeared to be losing flesh and had for some time complained of epigastric distress. Her breath was extremely offensive, the face was puffy, the legs and feet were very edematous and there was light general edema elsewhere. There was some general glandular enlargement, particularly involving the glands of the neck. There was a pleural effusion on both sides. There was a large mass about half the size of the fist in the lower part of the left side of the epigastrium which was evidently attached to the liver. There was, also, a smaller mass to the right of and below the one first mentioned. The area of splenic dulness was apparently moderately increased. There was some slight abdominal effusion. The urine varied in amount, contained albumin in amounts varying from traces up to 3 grams per liter. There was usually a little pus in the sediment, together with a considerable number of epithelial cells and numerous bacteria, but no red bloodcorpuscles. Hyaline and slightly granular casts were occasionally found. The eyes were in a condition of high myopia and showed the remains of an old kerato-linitis. There was absolute deafness in the left ear and impairment of hearing in the right ear. The tympanic membrane on the right side presented a cleftrix from the healing of a large perforation. The tonsil and palate on the right side were joined by a band which was probably the result of previous syphilitic ulceration. The tonsils were somewhat enlarged and there was chronic atrophic pharyngitis, chronic atrophic rhinitis and eczema of the nasal vestibules. Because of the child's severe deafness the presence of an evident ozema and the discovery of the scars of an interstitial keratitis in both corneae it was decided to treat the case as one of gummata of the liver and the child was put upon daily inunctions of half a dram of blue ointment and was given potassium iodide in doses of 3 grains 3 times a day, increased one grain per dose. Under treatment the pleural and abdominal effusions gradually disappeared, and the liver although remaining enlarged and hard, presented no evidence of the existence

of a mass. Six months later, except for the deafness, the nasopharyngeal trouble and the corneal opacities, the child would have been considered to have been practically in complete health. In the absence of definite knowledge of her condition in early infancy and since there were no positive signs of hereditary disease, it is quite possible that her syphilis may have been acquired after birth, although the author thinks that this is impossible. The case is a very instructive example of the necessity in late childhood as well as in adult life and infancy, of keeping in mind the possibility of a syphilitic origin of severe disease of the liver whether this seems to be mere chronic or has the clinical appearance of a new growth. [J. M. S.]

3.—Bainbridge reports the case of a boy, aged 3 years and 6 months, who had a small gangrenous ulcer to the right and left of the center of the external surface of the superior alveolar process extending onto the upper lip. Under chloroform anesthesia $\frac{1}{2}$ of the body of the upper jaw on either side was removed. The under surface of the lip was thoroughly curetted and cauterized with pure nitric acid. At the end of a week a gangrenous area appeared in the left cheek, and at a second operation the larger part of the lip was removed and more of the superior maxillary bone was curetted away. Later on new areas of gangrene appeared in various parts of the mouth and high up at the base of the skull. The temperature increased, the pulse became more rapid and feeble and the child died from exhaustion. After death it was found that all the bones of the face were diseased and that the necrosed tissue extended to the base of the skull and involved part of the body of the sphenoid bone. Another patient was a boy, aged 16 months, who after an attack of whooping cough had a tender mouth, along the upper jaw on account of which one incisor tooth was removed. Two days later an ulcerated patch appeared on the upper lip directly to the left of the median line. Under chloroform the bone was found to be soft and spongy and of a grey color. The diseased tissue was entirely removed and pure nitric acid was applied over the entire surface on the cavity of the bone. The wound was packed with gauze and irrigated every half hour with hydrogen peroxide, followed by boric acid solution. Full diet, strychnin and whisky were given and the patient recovered. [J. M. S.]

4.—Dermatitis herpetiformis is much more common in childhood than is generally supposed. Gotthell reports the case of a girl, aged 9 years, who had suffered from the disease for 5 years. When the eruption first appeared it was spread over the entire body, looked like measles and was called contagious. The face, hands and legs were the regions chiefly involved, but occasional patches have appeared upon the body. All the attacks commenced with severe itching of the part about to be affected. This symptom lasted for several days before the first sign of dermatitis appeared. Then there was a sudden eruption of grouped vesicles, which were surrounded by a very small amount of inflammation. The vesicles finally ruptured and their secretion dried up into dirty scabs which left a reddened and perhaps slightly excoriated surface behind them when the fell off. The pruritis diminished and disappeared as the period of quiescence set in. A second case occurred in a boy, aged 12 years. The attacks came on at very frequent intervals, sometimes only a few days apart, and were distinctly bullous in type. They always began on or around the genitals and thence extended to the abdomen and limbs. Treatment is very unsatisfactory. General tonic and hygienic measures, and when possible change of air and scene are more efficacious than drugs in postponing and preventing relapses. Locally any of the bland or cooling salves or ichthyol in 5 or 10% solution or ointment may be employed. [J. M. S.]

5.—Ray reports a case of abscess of the ethmoid bone and the antrum of Highmore occurring in a child, 4 years of age. The condition was cured after an operation.

2.—Byron Robinson discusses the relation of the appendix to the psoas muscle in 300 male and 118 female adult autopsies. In this paper the topographical anatomy of the appendix and cecum is carefully considered and many interesting illustrations presented. The author so frequently found the appendix adherent to the psoas muscle and free from adhesions when situated elsewhere that he strongly inclines to the conclusion that trauma of the psoas muscle is most productive of appendicitis. The appendix is considered the weakest segment of the intestinal canal.

[J. H. G.]

3.—Charles Lester Leonard considers the Roentgen method of diagnosis, in detecting and excluding renal and ureteral calculi. He asserts that many patients lose the functional activity of one kidney because an impacted calculus is not recognized. The impaction results in anuria which leads to atrophy and destruction of the kidney. Since the clinical aspect presented by recovery and by destruction of the kidney substance after impaction is the same in both instances a diagnosis of the condition is difficult. This position has been confirmed many times by post-mortem examination and the X-ray has shown impacted ureteral calculi to be more frequent than has heretofore been suspected. Attention is called to the varying symptomatology of renal calculi. A diagnosis of movable kidney, of nervous dyspepsia and of other conditions has been made when the real cause, as shown by the X-ray, was a calculus. In five cases submitted to the author for a confirmation of a positive diagnosis of calculus no calculus could be found by the X-ray and none by subsequent operation. It is no longer necessary to open a hydronephrotic kidney before first of all locating the calculus in the ureter. Reference is made to cases in which the X-ray has shown the presence of a calculus remaining in the kidney after one calculus had already been removed by operation. In four cases examined calculi were present in both kidneys or ureters. The Roentgen method is the only means excepting double exploratory nephrotomy by which it is possible to exclude calculi from an apparently healthy kidney. A calculus which produces complete obstruction is most dangerous because it produces oftentimes so few and indefinite symptoms. Another advantage offered by the X-ray is the fact that a calculus can be diagnosed and removed while it is yet small and before it has produced much change in the kidney structure. The author considers the negative diagnosis by the X-ray in proper hands as absolutely correct. He has examined 136 cases of suspected renal or ureteral calculi and made a negative diagnosis in 100. In but one of these has the diagnosis been disproved by operation and in this case the plate was misplaced and the reading of the negative defective. If the rays "will differentiate between the shadows of tissues less dense than the least dense calculus all calculi will be detected." The differentiation of the tissues in the lumbar and pelvic regions is the basis upon which rests the negative diagnosis. Attention is called to the necessity of using the Bigelow evacuator before operating for small ureteral stones because these minute calculi very readily slip into the bladder. [J. H. G.]

4.—L. L. McArthur reports a case of ileus due to vascular obstruction. If cardiac valvular vegetations, syphilis, endarteritis, etc. produce occlusion of blood vessels in the brain and other viscera why not in the superior and inferior mesenteric arteries? Ileus embolic and throm-

botic are considered. Embolic ileus from obstruction of the superior or inferior mesenteric arteries or other branches is rare, but when it occurs it necessarily means gangrene of the bowel since here there is no collateral circulation. Trauma or disease of the blood vessel wall may produce thrombosis resulting in ileus. Thrombosis of the mesenteric veins is most frequently due to an infective phlebitis which originates in the intestinal mucosa. Hematemesis and blood in the stools is a more constant symptom, of course, when the obstruction is venous. In this condition too, there is much greater exudation from the blood vessels and a more ready infection from intestinal bacteria. When there is obstruction of the arterial supply the bowel dies so rapidly that there is no time for the throwing out of plastic lymph on the peritoneal surfaces, the bowel in this case presenting a shiny, smooth, and black appearance. It is strongly urged upon the surgeon to go well above the apparent gangrene in resecting the bowel for ileus due to vascular obstruction. The most constant symptoms of this condition are described as follows:

(1) Blood seen either in the washings from bowel, in bowel movements or in the vomitus, unaccompanied by the tumor of intussusception.

(2) Colicky-like pains, associated with pains in back and lumbar region.

(3) Early collapse if the embolism has been sudden or extensive.

(4) Cardiac disturbance, arrhythmia, great frequency, albuminuria. [J. H. G.]

5.—D. A. K. Steele discusses the symptomatology and treatment of mechanical obstruction of the fecal current. The symptoms of mechanical obstruction are said to be remarkably uniform if studied before they are masked by the administration of opium. The differential diagnosis between mechanical obstruction and that due to other causes is also discussed. [J. H. G.]

6.—A. J. Ochsner discusses the question of ileus caused by neoplasms. The author's experience in operations for obstruction due to neoplasms has been such as to impress him with the great seriousness of this condition. Carcinoma is the most frequent new growth producing obstruction of the intestine. The neoplasms may originate in the ovary, the stomach, the pancreas, the omentum, or else in the mesenteric glands. Carcinoma is most common in the rectum, next in the upper colon, and next to this in the duodenum. The author has found sarcoma, myoma and myo-sarcoma most frequently to occur in the small intestine while the benign growths, lipoma, adenoma and fibroma are most commonly found in the colon. Not infrequently some undigested portion of food lodges at the seat of disease, producing acute obstruction. Although the symptoms characteristic of the neoplasm develop slowly, the onset of obstruction in these cases is usually quite sudden. Vomiting is present and if it comes on directly after the beginning of the obstruction the neoplasm is probably high up in the intestinal canal. Great pain usually follows the administration of cathartics. Peristalsis can occasionally be observed and is of the greatest value. Auscultation the author has not found a very satisfactory means of locating the obstruction. The history of the patient is of great value in making a diagnosis. The patient generally gives a history of evacuating large amounts of mucus and a severe attack of obstruction is not infrequently preceded by subacute attacks. The age of the patient is of importance as it is seldom that we find obstruction from neoplasms in patients under 40 years of age. The differential diagnosis of the condition is next discussed. In outlining the treatment the author lays stress upon the fact that both food and cathartics should be prohibited in every form of ileus. Where there is great distension from obstruction due to neoplasm it is recommended that the pharynx be sprayed with a 2% solution of cocaine, and gastric lavage be performed. Elevation of the foot of the bed should also be done. As soon as the distension is lessened operation should be performed. If a tumor can be felt it is well to make the abdominal incision directly over it. If the intestines are found greatly distended, so much so as to interfere with work, a coil should be brought out of the wound and a glass drainage tube inserted and fixed with a purse-string suture. In evacuating the bowel in this way it is well not to eviscerate because the pressure of the abdominal wall aids in the evacuation. When the growth is not found at once it is well to search the intes-

tinal tract systematically. If the growth is in the intestine primarily and there is no lymphatic movement a resection done three inches away from the growth may be made if the patient's condition will stand it, otherwise a short circuit should be instituted by lateral anastomosis.

[J. H. G.]

7.—Carl Beck reports an interesting case of fissure of the head of the radius. It was impossible to make this diagnosis at the time of the injury, but two days later a skiagraph which is here reproduced shows distinctly the fissuring of the bone. The author thinks that although a fracture below the head of the radius can be diagnosed without the use of the X ray, in this condition it would have been impossible to make a positive diagnosis without the employment of the rays. [J. H. G.]

8.—J. Shelton Horsley reports a case of excision of the cervical sympathetic ganglia for exophthalmic goitre. The author operated in this case on the theory, advanced by a number of authorities, that the condition had its origin in a derangement of the sympathetic centre. The patient was a Mexican woman 26 years of age. The patient suffered a great deal from cardiac palpitation and throbbing in the neck. The pulse varied from 120 to 140. Under chloroform amesthesia and with considerable difficulty the sympathetic ganglia on the right side were removed. The patient's pulse was very rapid during the operation, varying from 170 or 200 to a rapidity which could not be estimated. Owing to this condition it was thought unwise to attempt an excision of the ganglia of the left side. On two occasions during the operation the pulse suddenly dropped to about 72, which was supposed to be due to irritation of the pneumo-gastric. Subsequent to the operation her temperature rose to 104 and her pulse remained about 160. Vomiting continued at intervals for about 24 hours. The following morning her temperature was 100 and the pulse 110. The wound healed primarily and the patient left the hospital six days after the operation with a pulse of 92. She was greatly relieved from the throbbing which had been so annoying. Two months after the operation her pulse was 90 and she suffered from no throbbing or palpitation. The exophthalmos was greatly diminished but there was little change in the size of the gland. The patient has occasional pain in the right side of the head and face and a keloid has developed in the scar. Great improvement is considered the result of the operation and if the patient does not continue to progress favorably the author will recommend the excision of the left cervical sympathetic ganglia. [J. H. G.]

1.—After a resumé of the views of various surgeons, Koerte and Herzfeld state that medical treatment for gastric ulcer must always be tried. The diagnosis of gastric ulcer is reached much earlier than that of cancer. The sequelae of an ulcer of the stomach may be cicatricial stenosis of the pylorus, repeated hemorrhages, perigastritis, and perforation with peritonitis. 38 cases of stenosis of the pylorus from gastric ulcer were operated upon. In all cases symptoms had existed for a long time, even 30 years. The general condition was in all cases lowered, in some very markedly. Pain and vomiting were constantly present, and hematemesis or melena existed in almost half of the cases at some time. The ulcer was most frequently found in the pylorus. Abundant hydrochloric acid was present 21 times, lactic acid only 4 times. Of the 38 operations, gastroenterostomy was most often performed, (30 times, with 7 deaths). Resection was done 6 times. The Murphy button was not used once, as it is both compli-

cated and dangerous, for it may fall back into the stomach, and mechanically injure the ulcerated surface. Besides, stitches can be made just as quickly. Koerte and Herzfeld conclude that whenever medical treatment is unsuccessful, gastric ulcer must be operated. When cicatricial pyloric stenosis, with dilatation of the stomach, occurs, gastroenterostomy should be performed. When the general condition of the patient is good, the prognosis will be good. Besides, severe pain which has lasted a long time, with repeated small hemorrhages, also indicates operation. Resection is the radical treatment, yet gastroenterostomy will more frequently be done. When hyperacidity exists, more ulcers may appear, later, in the stomach or jejunum. Von Hacker's retrocolic method of performing gastroenterostomy was used. Should there be marked atony of the stomach, Braun's method of enterostomy may be done. Surgical treatment for acute copious hemorrhage from the stomach has been but doubtfully successful. The detailed history of the 38 cases operated upon, follows. 28 operations were for pyloric stenosis from gastric ulcer; 3 for cicatricial ulcers from caustics; 6 were resections; and one was a gastrotomy for hemorrhage. Ten operated cases for perforated gastric ulcers are also given in detail, only one of which recovered. The long list of authorities consulted follows. [M. O.]

2.—Before the nineteenth century, a wound penetrating the heart was considered necessarily fatal. Von Oppel experimented upon rabbits, introducing a needle into the heart, in some cases without operation, in others after having first exposed the heart by opening the pericardium. From his experiments, the technique of which is given in detail, von Oppel concludes that rabbits bear the introduction of a needle into an unexposed heart better than when the heart has been exposed; that the best method of exposing the heart is through the sternum; that the narcosis must be deep at the moment when the heart is exposed; that if the needle is introduced in the left edge of the sternum, the left side of the heart is more often wounded; that a needle does not wander from the lungs into the heart; that a thrombus forms about the part of the needle projecting into the cavity of the heart, which is later supplanted by connective tissue; that the free point of the protruding needle may cause endocarditis of the opposite wall; and that while, in man, the cause of death after the penetration of a foreign body into the heart seems often to be primary hemorrhage, this is almost never observed in rabbits. After a review of the surgery on the subject, von Oppel decides that a needle introduced into the human heart must be immediately extracted; that exposure of the heart for its removal will not always be necessary; that after the first few days exposure of the heart will be dangerous; that the needle can, under favorable circumstances remain in the heart; and that, to extract larger foreign bodies, the heart must be exposed. The literature is cited and seven drawings are given.

3.—Will be abstracted when completed.

4.—A quantity of splints had been devised for fractures of the carpal end of the radius. The discovery of the Roentgen ray made plain the manifold character of this fracture. Beck studied 104 cases, in 21 of which the head of the ulna was also fractured. 16 of them were fissured fractures, and were only recognized by the Roentgen process. In only 4 cases was even slight motion perceptible upon palpation. The Roentgen rays will perhaps show a fissured fracture when only a contusion has been suspected. And the position of the fragments may become plain under the Roentgen ray, thus facilitating treatment. After the fracture has been dressed, a Roentgen photograph will show the position of the fragments. After four weeks have passed without union, a Roentgen picture will indicate the operation required, and other photographs, taken a year later, will demonstrate the result. [M. O.]

5.—Mulert describes the salient points of a multiple endothelioma of the scalp, already reported by him four years ago, to show that Lubarsch, who not only criticized his work, but considered the tumor cancer, was wrong. [M. O.]

6.—Total extirpation of the larynx is by no means the dangerous operation now that it formerly was. After a description of the improved methods of operating, which have reduced the mortality to 10%, von Hippel reports the case of a man aged 40 years, who had neither tuberculosis nor syphilis. For 9 weeks he had noticed hoarseness, cough, with expectoration and pain in the throat, not, however, upon swallowing. Otherwise he felt well. Aphonia

existed at times. The area about both arytenoids was red and swollen, but there was no ulceration. Between them was a semicircular tumor, coming up to the vocal cords. A pleco was excised, which, on examination, proved to be **sarcoma**. Tracheotomy was performed, then total extirpation of the larynx by Foederl's method. Nine days later, an abscess was discovered in the wound, so that a secondary operation was performed. Six weeks later he was well. A year after operation, he is in excellent health, speaks in a whisper, but complains of no throat symptoms. There are as yet no signs of recurrence. Further examination revealed that the tumor was a round-celled sarcoma. Though the operation was finally successful, von Rippel thinks that its dangers are much greater than its advantages, and believes that he would never employ it again. Infection is bound to follow, due to the expectoration from the necessarily concomitant bronchitis, and the tension of the sutures is so great that the tracheal stump receives insufficient blood, so that gangrene becomes inevitable. The result, after two months' suffering, is no better than that achieved by Gluck's method, inside of two weeks. [M. O.]

7.—Staffel reports the case of a man of 43, who fell backward from a height of 5 meters. He landed with both hands behind him, under his body. When Staffel saw him, two months after the accident, his right hand was comparatively well, but the left hand showed a swelling on the palmar surface, near the head of the radius. All movements were normal except flexion, which was impossible. A Roentgen photograph showed the scaphoid bone broken into two pieces, both of which were displaced (one upon the end of the radius), and the semilunar bone also displaced. While the upper half of the scaphoid was palpable, the semilunar bone could not be felt. Even after two months of medico-mechanical treatment, the upper fragment of the scaphoid remains displaced, and flexion is yet impossible. Staffel has also seen a case of luxation of the semilunar bone alone. Only 15 cases of luxation of both scaphoid and semilunar bones were found in the literature. [M. O.]

8.—A few years ago, Professor Bobrow advised closing the sac surrounding an **echinococcus** cyst of the abdomen, after the cyst has been removed, returning the sac, closed, into the abdominal cavity, and then suturing the abdominal wall. The advantages of his method are that the wound heals quickly, without long suppuration; that there is no open wound, and so no secondary infection; that no fistula can follow; and that no cicatricial adhesions can occur between the abdominal wall and the abdominal viscera. Its disadvantages are the probability of recurrence, the stitches left in the sac, and the possibility of suppuration in the closed sac, with later perforative peritonitis. As suppuration in the closed sack is common, Rasumowsky employs double crossed sutures through the abdominal wall, closing the sac, and suturing it to the abdominal wall with silver wire sutures. These are easily opened, should suppuration occur, and the sac lies close beneath the abdominal wall. Rasumowski operated upon 26 cases of echinococcus cysts, 15 of which were in the liver. 18 of these were treated by opening the cyst, which was then sutured to the abdominal wall. Only three of them died. The other 8 cases were operated by the Bobrow method, with one death. The 26 case histories follow in detail. [M. O.]

ZEITSCHRIFT FUER HEILKUNDE.

1901. (22 Volume, No. 3.)

1. The Study of Congenital Hernia. CARL BAYER.
2. Inferior Peritoneal Adhesions. JOSEF ALTENEDER.
3. Resection of the Esophagus with Primary Circular Suture for Cicatricial Stenosis. THEODOR ESCHER.
4. Enteroplasty. TRNKA.
5. The Diagnosis and Differential Diagnosis of Extrauterine Pregnancy. JOSEF FABRICIUS.

1.—Bayer, from post-mortem examinations, believes a hernia to be **congenital** when its sac is formed by an unobliterated vaginal process; when the vessels, which are to form the spermatic cord are still separate; when the cremaster muscle forms the next layer of the sac; when the

aponneurosis of the external oblique muscle shows no opening, no external abdominal ring existing; and when the contents of the sac are at all peculiar. Bayer reports three more such cases, one in a boy of 11, the others in men of 18 and 34, in all of whom radical operation was done with success. In each, enough of the above mentioned characteristics were found to make the diagnosis of **congenital inguinal hernia**. The contents of the sac in every case were masses of omentum. [M. O.]

2.—By **inferior peritoneal adhesions** Alteneader means those pseudo-ligaments which are often found attached to the descending colon or the sigmoid flexure. These adhesions are sometimes also attached to the appendix, cecum, ascending colon, ovaries, or other neighboring abdominal or pelvic viscera. Its causes are varied. The symptoms may be many or few, and are extremely variable. When the female generative organs are affected, there is a symptom complex which permits easy diagnosis. Out of 42 cases of inferior peritoneal adhesions, the condition was correctly diagnosed before operation in 35 cases. Intestinal occlusion is rarely caused. **Laparotomy** was performed in all cases, the adhesions being freed. Only one case was fatal. 12 were wholly cured; 18 improved; and 3 unimproved. The eight others disappeared after operation, so that the final result is not known. In three cases a second operation was necessary. The adhesions were attached to the uterus or adnexa 23 times; to the appendix 33 times; to the bladder 9 times; to the sigmoid flexure 7 times; to the small intestine and omentum 6 times. There were tumors found in 8 cases; hydrosalpinx in 6, and tubo-ovarian cysts in 2 cases. The generative organs were free from adhesions in 17 cases. Only two of the 42 cases occurred in men; the age varied from 20 to 50; 29 women had never borne children; and 19 complained of troubles with menstruation. Chronic constipation existed in 10 cases. Inflammatory processes, tumors, former operations, etc., explain the occurrence of the adhesions. Yet in 13 cases, neither the history nor the operation made clear the cause. They may have been fetal, or have followed a disease which had run its course long before. In 13 cases the adhesions were primary, from acute inflammation. Secondly, any inflammation of an organ covered with peritoneum, or even a slight hemorrhage in such an organ, may cause the formation of an adhesion later. Pain is noted, occasional, and well localized. Many cases follow appendicitis. Operation is the only successful treatment. Details of the 42 reported cases follow. [M. O.]

3.—Escher was able to find but 14 reported cases of **resection of the esophagus**. After reviewing the literature, he reports the case of a woman of 48, who had become syphilitic from her husband, 15 years before. She had had mixed treatment at that time. Examination showed a **stricture of the esophagus** just below the larynx. Symptoms had only existed for half a year. **Esophagostomy** was at once performed. But the stricture, which was about 1 cm. in thickness, situated at the level of the fourth tracheal ring, was impermeable to all sounds introduced from above or below. Resection of the esophagus with primary circular suture was then performed, a piece 1½ cm. long being extirpated. Six weeks later she was well, and has always been able to swallow perfectly since. Examination of the excised stricture showed thick, cicatricial tissue. Though she showed no other sign of syphilis, yet no other cause for the stricture could be found. It is therefore possible that ulceration had occurred in the esophagus, followed by a scar, which had gradually contracted until occlusion of the esophagus occurred. The operation was a success, in spite of slight suppuration in the periesophageal connective tissue. [M. O.]

4.—Trnka reports the case of a soldier, aged 22, in whom **colostomy** had been performed for inflammation of the appendix, cecum, etc., with perforation of the ascending colon and circumscribed peritonitis. By a subsequent operation, the bowel was made permeable so that the opening in the anterior abdominal wall was useless. Trnka made

a long bridge flap of the skin, muscle and fascia, which protected in silk, was isolated for two weeks. Then, after emptying the intestines, and disinfecting the bowel, a semicircular flap was cut outside and below the opening. The bowel was closed off by the outer, lower skin flap, and the bridge flap was brought over it. Healing by first intention followed. Plates accompany the article to explain the operation. Trnka believes the skin to be the best substitute for the mucous membrane of the intestinal wall. A bridge flap alone will be strong enough to withstand the intra-abdominal pressure. Trnka advises the plastic operation both for small and large defects of the bowel and abdominal wall. [M. O.]

5.—There seems no doubt that **extrauterine pregnancy**, like cancer, appears far more frequently now than formerly. Fabricius has seen 84 cases in the last 8 years. The history, the hemorrhage, the decidua-cells found, the pain, the growing tumor, and the hematocele, (peritubal retro-uterine, or antiuterine,) will make the diagnosis of extrauterine pregnancy. It is commonly tubal, but may be tubo-ovarian, abdominal, or tubo-uterine, rarely. The uterus enlarges as the fetus grows. Vaginal examination will reveal a large retrouterine hematocele very much like a retroflected gravid uterus at three months; like a cyst in Douglas' pouch with hematometra and amenorrhea; like a soft myoma in Douglas' pouch; like an extrauterine pregnancy which has again begun to grow; or like parametritis or perimetritis exudate. In all, the uterus will be found below the symphysis pubis. The differential diagnosis becomes more difficult as the tumor grows larger. Small tumors of the adnexa, especially pyosalpinx, may easily be taken for extrauterine pregnancy. Or a tubal pregnancy may lie before or behind the uterus so that a normal pregnancy is suspected. Or, in a patient once operated upon for tubal pregnancy, the hematocele may appear upon the opposite side, (the side from which the tube had been removed), to that on which the second tubal pregnancy had occurred. Occasionally intrauterine pregnancy may be mistaken for extrauterine pregnancy. For the uterine muscle may become so atonic as to draw out of the neck of the uterus, so that the body of the uterus is supposed to be the extrauterine pregnancy. This also is the case when the neck of the uterus has hypertrophied. Pregnancy in one horn of a uterus bicornis will be mistaken for a tumor. Finally an extrauterine and an intrauterine pregnancy may co-exist. The ages of the patients seen by Fabricius varied from 23 to 44 years, but the great majority of extrauterine pregnancies occurred before the age of 20. 63 of the 84 patients had borne children; in four of them extrauterine pregnancy had already occurred. Detailed histories of many of his cases, with diagrams, are given to illustrate the conditions mentioned. Extrauterine pregnancy was found upon the left side 51 times, and 31 times on the right. The causes are as yet not exactly known. Gonorrhea, puerperal disease, tubal inflammation, bands in the tube, etc., have been noted. The uterine sound should be but little used, (only just before celiotomy) as it may cause perforation or abortion. Fabricius has reviewed the literature thoroughly, and states his facts in detail. [M. O.]

1.—(See editorial).

2.—Ibrahim calls attention to the fact that **acute yellow atrophy of the liver** is a condition that in all probability can be caused by a number of infectious agents. The fat in these cases is apparently derived from the degeneration of the liver parenchyma, and varies in quantity according to the duration of the process. He has interested himself particularly in the forms of degeneration that occur, and after a study of the reports in the literature, reaches the conclusion that there may be proliferation of the liver cells that have remained normal, or of the epithelium of the interlobular biliary vessels, or of the interstitial connective tissue. The last form is really reparation rather than regeneration.

The paper is still unfinished. [J. S.]

3.—The patient, a man of 66 with senile dementia and progressive cachexia, developed swelling of the right cheek and the tongue. This continued to extend, necrosis appeared, and a fungous growth developed on the inner side of the mouth. The cheek was perforated, the perforation extended and the patient finally died with symptoms of sepsis. At the autopsy atheroma of the carotids was found; fibrous degeneration of the heart muscle; and two saccular aneurysms of the abdominal aorta. In addition, the fungous growth had extended to the pharynx, esophagus, larynx and trachea, and had caused extensive ulceration. Cultures gave an unmixd growth of *saccharomyces*, although numerous cocci were found in the smear preparations. There were two causes for the development of noma. First, the mycotic stomatitis, and second, the pressure of the molar teeth upon the cheek. In addition the arterio sclerosis should be regarded as a predisposing cause. A full literature is appended. [J. S.]

4.—Cuno, after considerable experience with diphtheria antitoxic serum has reached the conclusion that it is useless to await the results of bacteriological investigations before injecting the serum. When intubation is necessary it is his custom to leave the tube in position for 100 hours, and then if it cannot be removed without the development of symptoms of stenosis tracheotomy is performed. He reports the statistics of 31 children on whom he used intubation, although there were indications for tracheotomy. Twenty-one of these were cured, 8 died, and 2 are still in the hospital under treatment. Of these 31 cases, however, 21 subsequently required tracheotomy. In 4 cases the results were unfavorable, that is to say, the children were left with more or less narrowing of the larynx. Two of these cases were readily relieved by sounds; the third, subsequently required laryngotomy and the fourth died at its home from gradually progressive stenosis. [J. S.]

5.—Bähr calls attention to the great caution which should be exercised in giving certificates of injury in cases of **fracture of the pelvis**, and mentions some of the serious results which may ensue, although objectively there may be little disturbance. [J. S.]

6.—Quadflieg reports 3 cases of **ovarian hernia**. The first, a child of 2 months, well developed, had a hard, painful tumor in the left inguinal region. At the autopsy a cystic degenerated ovary was found in the hernial sac. The second case, a child of 3½ months had a similar condition, and at the operation a gangrenous ovary was found in the sac. Both of these cases were evidently congenital. The 3rd case, a woman of 40 years, pregnant for the 9th time, came to the hospital complaining of a painful lump in the right inguinal region, which has existed for 9 years. Through all this time she had suffered from gastric disturbances and constipation. At the operation the sac was found to contain the right tube and ovary. It is interesting that in all these cases percussion over the tumor gave flatness. [J. S.]

7.—Schmidt states that the virulence of the contagion of scarlet fever may endure for a very long time. He mentions one case in which infection occurred 8 weeks after the symptoms had subsided. He reports a case of his own occurring in a woman 24 years of age, whose husband 11

weeks previously had had a slight attack of scarlet fever, after which he had not bathed. She was delivered of a healthy child and afterward placed in the bed that had been occupied by her husband. The next day but one she had a slight chill followed by a suspicious eruption and a high fever. The following day the disease was developed in typical form. The husband was then examined and intense desquamation was found on his skin. The interesting features are the long period during which the husband remained capable of conveying the infection, and the very brief prodromal period in the patient. [J. S.]

8.—Meussel suggests that in operations for goitre it is desirable to split the gland horizontally, and to leave the lower portion *in situ*. He has employed this method for 7 years and has had no bad results. [J. S.]

9.—Leusser in conclusion of his article, reports 5 additional cases, in all of which considerable improvement occurred. Treatment consisted of the application of various forms of baths, the maximum temperature being 27° or 28°, gradually reduced to 21° R. In some cases massage, active movements, and respiratory gymnastics were of value. Usually the duration of the treatment lasted from 4 to 6 weeks, and required from 25 to 30 baths. The cases that may be treated with advantage are: Valvular lesions, asthenic hearts, toxic hearts, cases of cardiac dilatation resulting from various forms of anemia, arterial sclerosis, and occasionally fatty degeneration of the heart. Cases that are not suitable are all in which there is an acute febrile disease of the heart, cardiac or vascular aneurysms, and heart failure with edema. [J. S.]

WIENER KLINISCHE WOCHENSCHRIFT.

April 4, 1901. (XIV Jahrgang, No. 14.)

1. Bacteriology in Making an Etiological Diagnosis. ED-MUND NEUSSER.
2. The Causes of Human Botryomycosis. R. von BAR-ACZ.
3. Intestinal Hemorrhage after Replacing Incarcerated Hernia. JOSEF PREINDLSBERGER.

1.—While bacteriology has shown the causes of certain diseases, it has not by any means differentiated the existing varieties of micro-organisms from one another. But it has shown different localized processes to be the same disease. Nowadays the physician must not only consider a disease clinically, but bacteriologically also, especially as regards the cause. Yet bacteria are often found in perfectly healthy individuals. When the bacteria are seen in the blood, however, no doubt can exist; for then the bacteria must be the cause of the existing condition. But nearly all bacteria have their "doubles" to mislead the physician. Excellent as have been the results of the serum reaction, the possibility of some people being naturally immune, from idiosyncrasy, must not be overlooked. Nor does every case of tetanus, which has been cured by the use of antitoxin, show traces of the antitoxin in the blood serum. The changes found in the blood are not typical of any one special kind of bacteria. Leukopenia, with a diminution of the fibrin coagulation and a positive Widal reaction, would almost lead to the diagnosis of typhoid fever, yet the same condition can be brought about by the colon bacillus, or in psittacosis. Besides, a positive diazo-reaction in lung diseases shows mixed infection, being negative when phthisis exists. Bacteriology has shown that diphtheria is a purely local process. It has been of great value in Vienna, recently, as finding the pest-bacilli prevented the occurrence of an epidemic of pest. By aiding in the diagnosis, it has assisted the prognosis and indicated the treatment. Neusser reports the case of a woman of 50, with acute jaundice. Suddenly, three days later, she had a chill, her blood showed increased fibrin coagulation, polynuclear leukocytes, and diminution of the urinary chlorides. There were no signs of pneumonia. Two days later a diastolic murmur was audible over the aorta. Unconsciousness followed, with meningitis and death. Neusser had diagnosed cholelithiasis, endocarditis and meningitis pneumococci. The autopsy confirmed the diagnosis. To show the danger of this sort of diagnosis, Neusser reports another case typical of miliary tuberculosis, which proved to be actinomycosis of the appendix, liver and lungs. Pigment, which had not been noted, was present about the nodules in the choroid, which proved the diagnosis of tuberculosis wrong. There is no doubt that bacteriologists, with all their care, have already been

deceived in the results obtained. Yet the fact remains that bacteriology, hand in hand with pathological anatomy, is becoming more and more an aid to exact diagnosis. [M. O.]

2.—Botryomycosis and staphylococci have been found in the small pedunculated growths rarely found upon the hands or fingers. Von Baracz reports the case of a girl of 12, upon whose thumb a small tumor grew. This was extirpated with cocaine anesthesia. From the tumor streptococci and staphylococci grew in pure cultures. The tumor was a polyp-like myxomatoid fibroma. Von Baracz concludes that not only the botryomyces, but the staphylococcus and streptococcus may produce these tumors. [M. O.]

3.—Hemorrhage after an incarcerated hernia has been replaced in the abdomen seldom occurs. Preindlsberger reports two uncertain cases, and two certain cases, out of six years experience. One of the two cases recovered, the other died six days after operation, with hemorrhage. A thorough review of the literature is given. The prognosis in such cases is unfavorable. The treatment consists in the application of an ice-bag, and opium internally. The hemorrhage aggravates the low state of the general health, but is not itself the cause of death. [M. O.]

May 2, 1901. (XIV Jahrgang, No. 18.)

1. Lacerations of the Vaginal Vault During Labor. H. LUDWIG.
2. Syphilitic Dactylitis. FRANZ MRACEK.
3. The Question of Leukemia. WILHELM TUEBK.

1.—Will be abstracted when concluded.

2.—In syphilitic dactylitis the bone is affected primarily, the lesion then spreading to the soft parts of the finger. But as syphilis seldom affects the small bones, dactylitis is rare. Out of 50,000 syphilitics, Mracek has seen but 5 cases affecting the phalanges, and three of these were in children. In infants with hereditary syphilis, however, the condition is more common. Mracek reports a case of syphilitic dactylitis in a man of 30, in whom both fingers and toes were diseased. The affection first appeared six years ago in the left thumb. Three years later the third left toe, and a year ago both index fingers became affected. Now, besides, the right thumb, the right third and little toes are also thickened. Mercurial inunctions are given, alternating with potassium iodide. A Röntgen photograph had been taken, which showed the phalanges very pale, rarified, with distinct vacuoles in the bones. This appeared three years after the patient had acquired syphilis. There was an osteitis of several phalanges, the lime salts were withdrawn, and carious cavities formed. Then an inflammation occurred around the bones, with infiltration and edema of the soft parts. Mracek believes that potassium iodide alone is the best treatment. [M. O.]

3.—Tuerk reports more of his experiments to show that the ameboid parasite which Loewit claims to have discovered as the cause of leukemia is but a mass of remains of broken down lymphocyte nuclei. Tuerk proves plainly that the so-called parasites are not ameboid, not living, and not the cause of leukemia. [M. O.]

JOURNAL DES PRATICIENS.

May 11, 1901. (XVme, Année, No. 19.)

1. The Compression of the Fetal Head by Forceps. L. DEMELIN.
2. Mitral Obstruction from the Pressure of an Aneurysm of the Descending Aorta. S. E. HENSCHEN.
3. The Therapeutics of Hydrastis. E. TOURNIER.

1.—The amount of pressure borne by the fetal head may be immense. It may be due to the forceps, the pelvis, or both together. The pressure of the forceps is generally exerted in the diameter between its blades; the pressure of the pelvis is perpendicular to that. The latter occurs frequently, even in a normal pelvis. Demelin believes that care must be taken to prevent compression of the fetal head; that the forceps, applied obliquely, nearer the transverse than the perpendicular diameter, will be best; that a forceps must be used that will not slip; and that a Sims speculum may be used to protect the perineum during traction with the forceps. Finally, Demelin advises his modification of the Tarnier forceps, which will be serviceable in many ways. [M. O.]

2.—Henschen reports a most interesting case, a man of 18,

who had been under treatment for three years, with the diagnosis of **mitral obstruction** and subacute nephritis, with hydrothorax, ascites, and anasarca. He had had two attacks of erysipelas. The apex was in the sixth interspace, outside the midclavicular line. There was no thrill. Dulness extended to the right nipple, beginning above, 3 cm. below the suprasternal fossa. A prolonged presystolic murmur was audible, loudest over the pulmonary area. The right radial pulse was dirotic; the left small and tense. They were synchronous. Albumin, hyaline and granular casts were seen in the urine. There was dulness posteriorly on both sides, below the scapula, with rales. There was some purpura, with a few pustules. But no fever appeared until a few days before death. At the autopsy, liquid was found in the peritoneal, pericardial, and pleural cavities, (more in the right pleura than in the left.) The heart, hypertrophied and dilated, when raised, disclosed a tumor just above the diaphragm. There were no valvular lesions, but some myocarditis. The lungs were congested; an infarct was seen in the spleen; and the kidneys showed sclerosis. Theorta was somewhat dilated. Beginning 2 cm. below the subclavian, the aorta showed many plates of endarteritis, with a collection of **aneurysmal sacs**, all upon the anterior wall. Externally they looked like a thyroid gland, with its two large lobes. It exerted pressure only upon the left auricle and ventricle. It is difficult to decide whether the aneurysm caused the murmur. There seemed no cause for aneurysm, and there were no symptoms, from its position. The left auricle could not dilate on account of the aneurysm. The prominence of the precordia may have been due to the pressure of the aneurysm behind the heart. But an **aneurysm** in a laborer of 18 is rare; rarer still is **compression of the heart by an aneurysm of the descending aorta**. [M. O.]

3.—After reviewing the preparations of **hydrastis**, Tournier says that it is the main drug used to control hemorrhage. It is excellent in hemoptysis, epistaxis, purpura, hematemesis, enterorrhagia, and hematuria, but it is mostly employed in **metrorrhagia**. These uterine hemorrhages are divided into three classes, those of puberty, in which hydrastis is exceptionally effective; those of adult age, in which hydrastis, supplemented by local applications, works well; and those of the menopause or of old age, in which hydrastis may be of benefit. But it has no therapeutic effect in uterine cancer. Tournier advises but two preparations of hydrastis, the fluid extract, which is the best and most widely used, and hydrastinin hydrochlorate. They have also been used in bronchitis, endocarditis, nephritis, the vomiting of pregnancy, the neuroses, etc. [M. O.]

JOURNAL DE MEDECINE DE BORDEAUX.

April 14, 1901. (31me. Année, No. 15.)

1. Perilungual Eczema. W. DUBREUILH and D. FRECHE.
2. A Foreign Body in the Trachea. BRINDEL.

1.—**Eczema** occurs commonly about the finger nails. The matrix or the bed of the nail may be affected, primarily, or by contiguity from eczema on the back of the finger. The first sign is the redness of the supraungual tissue, which becomes painful to pressure. Rarely so much serum may exude that the nail is lifted up, and finally falls off. Striations will be noted in the nails, with punctiform depressions. But hemorrhage in the nail, or fissures may also appear. The whole nail may be raised from its bed, or a depression may appear in the median line. In chronic eczema the nails will be deformed. Eczema must be differentiated from psoriasis and thina. Three cases are reported, a supraungual eczema with punctiform depressions; an acute perilungual eczema of the matrix; and a chronic eczema of the matrix and bed of the nail. The treatment of **perilungual eczema** consists of boric acid or salicylic acid washes, and a dusting powder. In chronic inflammation, resorcin may give good results. [M. O.]

2.—Brindel reports the case of a child aged 7 years, who became suffocated after having eaten fried eggs. As the

dyspnea continued, with cough and vomiting, a physician was called in haste. Her breathing calmed down, and nothing was done. The next day the cough and dyspnea persisted, with bronchitis. Laryngoscopic examination was impossible as the child could not be held quiet. The muffled cough with rumbling respiration, most marked during expiration, suggested the presence of a **foreign body in the trachea**. A Roentgen photograph was taken, which showed a mass about half the size of a thumb, just below the glottis. It threw too deep a shadow for bread, yet too light a shadow for any metallic body. It was immobile. **Tracheotomy** was performed, and the foreign body removed with a curette. It was a bit of the hard edge of the eggs. The tracheotomy opening was sutured, no canula being left in, and the child quickly recovered. The voice always remains normal in these cases. The diagnosis is made from the muffled cough, dyspnea, and sudden onset. The foreign body could never have been coughed up in this case. A good light and a frontal mirror are needed for operation. Tracheotomy will be necessary in most of these cases, and rarely, as in this case, it will not be obligatory to leave a canula in the tracheotomy wound. [M. O.]

May 5, 1901. (31me. Année, No. 18).

1. Iodide of Arsenic in the Emphysematous Bronchitis of Children. R. SAINT-PHILIPPE.
2. A New Operative Procedure for Strabismus. CAMILLE FROMAGET.
3. The Study of the Portal Circulation in the Liver. SEREGE.

1.—In treating the diseases of the respiratory tract in children, Saint-Philippe has made the observations, first, that true asthma is very rare, and second, that chronic bronchitis does not occur. **Bronchitis** often recurs, or may be prolonged, but never becomes chronic. He considers emphysematous bronchitis the form most common among children. With this there is always some dyspnea, yet never marked asthmatic paroxysms. Some emphysema appears, but disappears again when the bronchitis is cured. When a child has many attacks, his bronchi become distended from loss of elasticity. In the chronic bronchitis of adults, on the contrary, bronchiectasis is due to rupture or atrophy of the elastic fibers. This bronchitis is commonly observed with the infectious diseases, especially in rachitic, lithemic, or tubercular children. As treatment Saint-Philippe has used from 5 to 15 drops of 1% solution of **iodide of arsenic** three daily, with meals, with much success. [M. O.]

2.—Fromaget describes the technique of his **modification of the operation of advancement of the eye-muscles, with tenotomy, for strabismus**. His article is illustrated to make the details of the procedure clear. He has had excellent results from it. [M. O.]

3.—From a dozen experiments upon animals and man, Sérége believes that the classic idea of but a single blood current in the portal vein from the intestines to the liver is erroneous; that in reality two currents exist, one from the mesentery to the right lobe of the liver, the other from the spleen to the left lobe; that these two currents do not mix; and that the liver is formed of two well differentiated lobes. After quoting 25 clinical observations from literature, and analyzing 188 livers from diabetic subjects, Sérége concludes that clinical observation, anatomy, comparative anatomy, physiology, pathological anatomy, and experiments all prove that a direct relation exists between each of the branches of the portal vein of the lobes of the liver; and that this relation of one branch to one lobe of the liver remains constant. [M. O.]

Disarticulation of the Knee.—Disarticulation of the knee presents many advantages over amputation of the femur above the knee. Dr. G. Chavannaz reports two cases in the (*Journal de Médecine de Bordeaux*, 1901, No. 21). One was a man of 63, in whom epithelioma developed at the site of an old fracture. The knee was disarticulated, and the patient recovered. The other was a man of 34, with tuberculous osteitis and osteo-arthritis. He also recovered after disarticulation of the knee. Both patients walk without a cane, using a simple wooden leg from the knee. Elliptical flaps were made. [M. O.]

Original Articles.

SPASTIC ILEUS.

By EDWARD QUINTARD, M. D.,

of New York.

Every day we are getting to recognize more fully the profound effect which the nervous system exerts on the various organs and elements composing the human body. In spite, however, of all that has been said, or that at present can be said, we are woefully at loss to interpret correctly countless clinical facts coming daily under our notice, yet which, unfortunately, many of us seem quite content to pronounce "nervous phenomena," a phrase which seems to be so seductive a morsel of ignorance and bliss, that folly frequently feasts where wisdom starves.

To the gastro enterologist, and especially to one who endeavors to unravel some of the mysteries of the intestinal neuroses, the fact that he finds himself constantly gazing into "the dark, unbottomed, infinite abyss" is only too evident, for the more he endeavors to untie this particular Gordian knot, the more intricate does it seem to get, until the investigator, unless he has the true spirit and a grim earnestness of purpose, finds that the term "nervous phenomena" has a particularly soothing sound.

There are many reasons why our knowledge as to the influence which the disordered or diseased nervous system exerts over the various organs of digestion has not grown apace. The following may be considered some of the chief of these:

First:—It is only in rare instances, and especially is this the case with the so-called "functional neuroses," that there can be a demonstrable pathology, because the patients either recover completely, or, if not, they die of some intercurrent disease, the symptoms of which entirely mask those of the functional neurosis, and if then it should come to an autopsy, it would be, in most cases, an absolute impossibility for the pathologist to say, if lesions were found in the nervous system, whether these changes in the nerves were the cause of the former supposed functional disorder, or whether these nervous lesions themselves had not arisen in the course of the last acute or super-imposed disease.

Second:—To the physiologist the problems which face him in the course of his investigations are particularly vexatious and trying. To begin with, in the case of "test animals" it is extremely difficult to obtain exact physiological conditions. The manipulation of the nerves must, in certain instances, be exquisitely delicate, and the dissection of the nervous system, especially of its minute ramifications, is a task that can be accomplished only by the most skillful and experienced—a keen eye, a steady hand and a cool head is the rare combination necessary.

Third:—I think this fact is too frequently lost sight of,—we should never forget that a well dog is not a sick man, and that although many sound and enlightening facts can be obtained, and many

helpful theories deduced from experiments on healthy animals, nevertheless, we must be extremely careful how we draw conclusions from such experiments, otherwise we may find ourselves repeating, like the good Master, Ludwig Traube, in that delightful anecdote as related of him by one of his greatest pupils, our own true and sterling Osler, "Wir haben nicht richtig gedacht."

As the object of this paper is purely clinical, I shall confine myself to a description of a few of the more interesting cases of "Spastic Ileus," that have already been reported from time to time, in, for the most part, foreign journals, adding two cases of my own. The names of the authors and their articles, together with the titles of articles dealing with experiments on peristalsis, are given in full at the end of this paper.

(1) **Jaccoud, 1867**, mentions the case of a young hysterical girl who had fecal vomiting for eight days, three or more such attacks occurring during each day. At the end of the eighth day they stopped. Ten days later patient contracted typhoid and died at end of third week. Autopsy—absolutely negative. In 1892 he saw another hysterical woman who had fecal vomiting and surgical interference was being discussed when it yielded to anti-spasmodics such as bella-donna, camphor, etc.

(2) **Voisin** reports a case of a young hysterical woman who sickened three times with symptoms of intestinal occlusion. Twice a cure followed through anti-spasmodics and purges, but in the third attack she died. The autopsy showed a purely spasmodic contraction of the intestines, nothing more.

(3) **Cherchewsky's Case**. "M. M., lawyer, aet. 42. Up to his entrance into the university, in 1860, perfectly well. The political troubles of that time made a deep impression on him and he became exceedingly nervous. He never had syphilis, but had had malaria, from which he recovered, but the malaria increased all his nervous symptoms and left him subject to constipation and dyspeptic symptoms, such as loss of appetite, belching and pain in the stomach, which latter, even at that time, had a predilection for the right side. These troubles gradually increased in intensity and frequency until, having reached a certain degree, they remained stationary 20 years, alternating with periods of brief yet perfect health. The symptoms were as follows: Coated tongue, noisy belching, loss of appetite, constant oppression in epigastric region, the abdomen was markedly distended, especially on right side, where the patient complained of a hollow and constricted pain. There existed obstinate constipation—intervals passing as long as 8-10 days without a stool, and when stools came they were in the form of isolated little balls or the fusiform masses 8-10 cm. long; when this was the case great effort had to be made at evacuation, manual aid being frequently necessary. In the intervals of well being which were quite frequent, the stools came suddenly and with ease, and were of larger volume both as to thickness and length. Believing that his trouble all came from his food, the patient began to refuse to eat, now this thing, and again that, and in general ate very little. As a consequence he became feeble, emaciated rapidly, and was subject to frequent attacks of vertigo. At the same time his work increasing, his responsibilities as a lawyer became very great. One day, after being constipated for 10 days, he felt a desire to go to the stool; the prodigious efforts which he had to make had no results—save that he expelled from his mouth a piece of excrement as thick as the finger and 8 cm. long, of a yellow color and characteristic odor. A fainting spell of very short duration followed this accident, but he recovered shortly and went to work. One hour and a half after this there was a copious and easy stool. When the patient came to us he presented a pale and exceedingly delicate appearance. There was nothing abnormal about the abdominal organs except that the abdomen itself was moderately distended, especially toward the right side. There was no pain on pressure over the epigastrium. Just below the umbilicus and a little to the right the patient experienced on hard pressure a dull pain which was propagated towards the region of the stomach and produced a slight nausea, as well as

*Read before the American Gastro-Enterological Association, Washington, D. C., May 1, 1901.

some belching the latter without odor or taste. The nervous system presented nothing abnormal.

Treatment. Belladonna $\frac{1}{2}$ t. i. d. Almost immediately produced normal stools. Codeine produced the same effect. The general treatment consisted in cold douches of 15° taken daily. In seven months the patient was cured.

This case was in all probability one dependent upon neurasthenia with its consequent disturbance in metabolism.

(1) **Rosenstein's Case.** "J. von der Moesel, a nine year old boy of blooming appearance, came to the clinic March 8th, 1882. His mother states that up to February 1st, 1882, he was absolutely well. Since that time off and on, he has had peculiar attacks. At first only once a week; later on several times a week. Up to the moment of the attacks the boy seemed well and happy; all at once he apparently would become unconscious for a moment or so, have convulsive twitchings and then under great terror void spherical fecal masses from his mouth. The closest inspection of the little patient revealed nothing abnormal physically; all his organs were seemingly sound. During the night from 9-10 P. M. he had, according to the nurse, slight twitchings of the face, arms and legs, during sleep, and on awakening, vomited a few scybala. During the following days, from the 12th to the 25th, the boy had so many attacks that both my assistants as well as myself had ample opportunity to observe the same."

"In the midst of happy play, just as if he felt an aura, he would run suddenly to his bed; or, being in bed and in the midst of a conversation with his neighbor, he would become suddenly quiet, next alternately bend and stretch his fingers a few times, until violent tetanic extension of both arms followed; then presently the two legs and feet would become involved, and trismus occurred, clonic convulsions of the masseter and marked grinding of the teeth having preceded these symptoms—finally, violent opisthotonus took place. After this had lasted for a space of time, the boy would awake, and under a feeling of great terror, would put his finger in his mouth, and take out 2 or 3 formed scybala and at the same time have stool, the scybala of which were of exactly the same appearance as those voided by the mouth. The individual scybalum had a length of 1.7-3 cm. and a circumference of 4.5-7.8 cm. At one time even he voided per os. a sausage formed mass 18 cm. long. One day a clyster of alenna was given him with the result, that, the masses voided per os., which as a rule were of yellowish brown, were colored dark blue. During the attack of opisthotonus his state of unconsciousness was such, that loud calling evoked no response."

"Artificial opening of the eyelids, however, was always sufficient to awaken consciousness and at times to stop the entire convulsive attack. The complete train of symptoms as given above did not always take place. Repeatedly there were seizures in which the tetanic extension of the arms alone took place. The attacks could not be produced by pressure on the nerves or arteries of the extremities. The fecal vomiting occurred for the most part after a severe attack, but at times this was not the case. Stool also occurred almost invariably simultaneous with the fecal vomiting, but not always. There was no visible peristalsis. It must also be mentioned that the boy was well nourished and that the abdominal covering was by no means thin. Following stool and vomiting the patient complained of pain in the abdomen, but at no particular point was there aught discernible at fault with the abdominal organs."

"The treatment consisted in large doses of bromide of potassium and clysters. By this means the attacks of convulsions which at first lasted two hours gradually became shorter and less severe. But up to the 28th of March they occurred together with fecal vomiting, the latter whether there had been stool or not. The last attack was on March 30th, after which the boy was with us four weeks without any attacks, and then only once after he returned home did he have a seizure."

(5).—**Dr. Paul Sandoz.** On October 3rd, Sandoz was called to see a strong, well-built man aet. 55 years, who up to date had been perfectly well. He was suffering from frightful pain in the abdomen, which had already lasted an hour. He was lying in bed and screaming with pain, covered with clammy sweat, the extremities were cold, the face anxious."

October 3d.—"The pains extend over the entire abdomen and radiate towards the back. There is nausea and uninter-

rupted vomiting. He at first vomited food, but later a bile colored fluid. There is also some tenesmus. Patient every minute demanded the bed-pan without being able to have a stool. Pulse weak, 60. No fever. Abdomen is soft—not painful; nothing abnormal can be detected. No hernia. Nothing in liver, kidneys, lungs and heart abnormal. Close questioning showed the patient to be suffering from tabes, although he never had syphilitic symptoms, nor was he alcoholic. Was given morphine hypodermically, and ether sulphuric, 3.0 Syp. Gummos, 20.0 Aq. Destill, 130.0 q. i. d."

October 4. "Next day patient was easier. Pains less severe, but the bilious vomiting continues. Pulse 65. T. 37°C. No stool. Very weak, but extremities no longer cold. Abdomen not tender, but more distended than in previous period."

October 5.—"No better. Abdomen more distended, but not tender and tympanitic all over. No stool. A Senna infusion is vomited. Clysters bring away only small hard fecal balls. Everything eaten immediately vomited. P. 46. No fever."

October 6.—"Meteorismus increases constantly, vomiting continues, bilious in character. Since the evening a continuous singultus. High lavage; no effect."

October 7.—"Since this morning fecal vomiting. The vomit consists of a yellow brown fluid in which are solid masses of the same color, and the whole has a characteristic fecal odor. The singultus permits of no rest. The abdomen is distended and is hard. At 9 A. M. gastric lavage; result, a large quantity of fecal fluid. Lavage until fluid returns clear. Singultus and vomiting stop after lavage. No stool. In the course of the afternoon the singultus and vomiting return, but lavage again checks it. No stool."

"This same condition lasts up until October 16th, the fecal vomiting lasting up to this date. It was always arrested for a time by washing out the stomach, which was done twice daily. The meteorismus was by that time enormous. Patient complained of very severe cramp-like abdominal pains. The prostration was great, voice broken. The patient was cyanotic and complained of a horrible taste in the throat and mouth. Since the 13th faradization of the throat has been tried."

"The condition of the patient was extremely precarious when, on the evening of October 16th, one-half hour after gastric lavage, he passed gas and shortly after expelled large quantities of fluid and semi-solid masses. Immediately the singultus and vomiting ceased."

October 17.—"During the night several more stools. Patient very weak but a great deal easier; the cyanosis and meteorismus rapidly disappeared and he made a rapid recovery."

(6). **Hoorweg.** A 26-year-old woman, since 12 years of age nervous, and for 15 years has had hysterical attacks. Grew worse at commencement of menstruation: then paraplegia; at 19 years of age anuria and vomited matter which had urine-like odor. After this fecal vomiting, and 6 years later mental disturbances. On admission, stupor, sensory and sensible anesthesia, analgesia, reflexes increased, pelvic organs sound, bladder and rectum empty.

Course: Morning stomach washings always contained remnants of evening meal, evening gastric washings often contained fecal masses. Injections of 1½ litres are often completely absorbed, 4 or 5 hours later vomit contains much fecal matter. Bladder proven by catheter to be empty, or else contains only strong concentrated urine. Faradization of rectum and bladder brings about undoubted betterment.

(7).—**J. Grundzach's Case.** In May, 1894, Grundzach was called to see a gentleman with whom he was personally acquainted, and whose age was something over 30. The patient complained of violent pains over the entire abdomen, complete stoppage of stool and wind, and loss of appetite. This condition, which had lasted for 24 hours, began after eating a hearty supper, and amongst other things the patient remembered swallowing a fish bone. He had taken calomel and castor oil without effect. There had been no stool and no gas passed, but there was an undefined pressure about the anal orifice. Examination of the patient revealed a distended stomach which was tympanitic on percussion; the abdomen was tender on pressure, but outside of a marked symmetrical distension of the intestinal tract, re-

vealed nothing abnormal. The face was anxious. Remembering the fish-bone, Dr. Grundzach inserted his finger with some difficulty in the rectum, and 8 cm. from the anal orifice detected a hard, beam like, transverse lying body, both ends resting against the intestinal wall, and so grasped by the latter, that it could not be moved without great pain. Finally he succeeded in getting hold of one end of the offending body, not without, however, a momentary violent pain to the patient, and gradually worked it downward, until, grasping it with 2 fingers, he withdrew a discolored fish-bone, 5-6 cm. long. Immediately upon the removal of the fish-bone the abdominal pains vanished, the abdomen became softer and there was scarcely any pain on pressure. Shortly after this the patient passed wind and several semi-fluid stools.

Grundzach remarks that it is very interesting to think that so sharp and large a body as this fish-bone could be swallowed without discomfort and pass the entire intestinal tract without hindrance until it reached the rectum where it caused an intestinal spasm at the point of lodgement. Furthermore, Grundzach contends it is strange that the pain was not localized in the lower part of the abdomen or in the anus, but over the entire abdomen, and that it should disappear on the instant that the fish-bone was removed.

(8) **Treeves Case.** A 24-year-old woman was admitted to the hospital because of fecal vomiting. Since 4 weeks stoppage of stools is supposed to have existed. At the beginning the symptoms bettered themselves, only to return in a few weeks more markedly. Patient now vomited the nutrient and oil clysters. Experimented by injecting methyl blue per rectum. Found that such injections, as was the case with the oil, were voided every time by the mouth, in less than ten minutes and in full quantity. Treeves diagnosed a gastro-colonic fistula and performed laparotomy. Found, however, absolutely normal conditions. After the operation the patient simulated the death agony, as usually conceived by the laity. All symptoms vanished on isolating the patient, i. e., when she had no public to play to. She was discharged cured.

Several months before this the patient had been twice operated upon for the same symptoms and diagnosis in the London Hospital. There also the symptoms disappeared after the operation, only to return in a few weeks. It is to be further noted that the patient was operated upon in Poland, and that she could in some unknown way raise her temperature to 50° C. Treeves prognosticated a still further operative career.

(9) **Tansini** reports a case of ileus spasticus following the operation for movable kidney. The case was that of a woman who two days after the operation was seized with severe abdominal pains, complete suppression of stool and flatus, a distended abdomen and great weakness. On the fourth day there appeared distinct and strong visible peristaltic actions; on the fifth vomiting; on the 6th, the condition was such a bad one that laparotomy suggested itself, in that all therapeutic measures had failed. On the 7th day the patient began to pass gas, then feces and recovered.

After being completely well for 3 months she complained of the same ailments as before operation, the consequence of which was that the other kidney was fixed in place. Directly after this there again appeared the symptoms of occlusion which lasted seven days, the vomiting, the visible peristalsis, the complete suppression of feces and gas appearing and disappearing at the end of the 7th day as suddenly as they had appeared.

(10) **Slajmer Case.** "It deals with a severe case of hysteria, as observed in a Sister of Charity, 26 years old, weak, anemic. Ever since October, 1887, she has been ill. She felt at that time, after a work of great exertion, pain in the left abdominal side, palpitation and pressure, and since has suffered from loss of appetite, flatulency and obstipation; for $\frac{3}{4}$ of a year anemia is supposed to have been present. In the summer of '89, according to account, there has existed inflammation of the kidneys with retention of urine and swelling of the feet. In the year of 1890, frequent vomiting, great faintness, pain after eating, and belching. Even at that time one physician was said to have diagnosed intestinal stenosis. These conditions grew better and worse several different times. The symptoms were especially severe in June, 1892, at which time, according to account, there were for 14 days severe pain, nausea, vom-

iting and tenesmus with retention of stool and wind. The patient described the pains as follows: 'In my left side it seemed as if something was torn; when I wished to make a step, there was always something like a thumb which came forth and pressed against the peritoneum.'

"This is supposed to have continued until August. There occurred also backache, headache, and fear lest she should become insane.

"In 1893 all the troubles returned, but as the patient was known to be hysterical not much attention was paid to her. Not until February, when there was an increase in the symptoms, did she come to the Surgical Department of the General Hospital at Lalsbach, February 26, 1893.

"She was at that time anemic to a high degree, but only slightly collapsed. The abdomen was very markedly distended, especially towards the left of the navel, where the examination revealed a greatly distended intestinal loop. According to accounts after the passage of both stool and wind had been absolutely arrested, for 8 days there occurred after the second days' sojourn in the hospital, vomiting of distinct fecal smelling matter. For this reason Dr. Slajmer undertook laparotomy on February 28th, 1893. His report was as follows: 'On opening the abdomen distended intestinal coils welled forward. The search for the obstruction was made principally towards the left, because the patient always complained of pain there; here there was found a part of the small intestine 20-25 cm. in length (which incidentally lies 2 m. beneath the flexura duodeno-jejunalis) band-like in form, and contracted to the size of a little finger. This part of the gut looked like the part of the intestine leading away from an obstruction. Nevertheless, as it was drawn forward, which was easily accomplished, it was shown that no obstruction existed. The intestine above the contracted point was distended to more than three times the normal size, the part below the contraction was of normal dimensions. The contracted part was brought out. Gradually it filled, and became similar in dimensions to the adjoining parts. But for a long time the boundaries of the formerly contracted intestine could be determined by its difference in color.

"No other cause for the fecal vomiting could be found. There was absolutely no sign of peritonitis."

"The course after the operation was a smooth one, and on the next day stool occurred."

"Several months later there were again hysterical ailments (Globus, etc.), and recently intestinal symptoms. Then followed undoubted symptoms of enteroptosis. At the end of October on account of especial sinking of the left kidney, nephrorrhaphy was done on this side with lasting results. The repetition of the former intestinal symptoms was, however, by no means affected by this. But after this there was a disinclination to undertake any hysterical methods of treatment the complaints were bettered or ceased."

"The conception that in this case the symptoms of ileus might be caused, by the movable kidney which existed at that time, although unrecognized, is excluded by the discovery made at operation. Because so even a contraction of the intestine involving so great a length could not result from such a cause, again, the conception that the nephroptosis caused the ileus is yet further weakened when one thinks that after the fixation of the kidney the intestinal symptoms reappeared as formerly. There rests, therefore, no doubt, that we have to deal with a purely functional disturbance of the intestinal tract."

Schloffer Case. (10) "Mrs. Marie Sellner, 28 years old, married, of Prag, had already on account of a severe hysteria been to many different clinics, and to many doctors in Prag for treatment. Dr. Funke, assistant in the Medical Clinic of Hofrath Pribran, had for many years on account of the peculiar symptoms which this patient presented, owing to her hysteria, taken an especial interest in the case, and observed her closely. I have to thank him for the information that during the course of the time in which he observed her, the patient showed the following hysterical symptoms: Concentric contraction of the field of vision, hyperesthesia in geometric arrangement, very variable paresthesia of the upper and lower extremities, distinctly painful pressure points beneath the mammae, distinctly painful ovarian pressure points, and painfulness on pressure along the spine. Stomach symptoms which for the time being led one to think of ulcer, which, however, passed very quickly over, and at times pronounced hys-

terical convulsions. Along with this it is to be observed that on account of a chronic endometritis of the body and neck of the uterus, Prof. Rosenstein had to remove the vaginal part of that organ. She was at the German University Polyclinic in May and June, 1897, on account of a hysterical and bloody cough (no evidence of phthisis). This lasted 6 weeks.

"At the same time there appeared bloody urine. The first assistant of the polyclinic, Dr. Kraal, drew off bloody urine by means of the catheter. On the 21st of June, 1898, the patient came with the assertion that for 5 days she had had no stool. She was given aloes and injections, and on the next day as these remained without effect she was given a lavage ofenna infusion and drastic purges. As these measures were absolutely futile, they were increased during the next few days. The general condition in the meantime was good, the cheeks were bright red, and there existed no especial distension of the lower abdomen; but presently nausea and finally vomiting set in. On May 26th, the patient vomited feces. Dr. Kral visited the patient just at this time at her house and was shown a great deal of feces in pieces and fragments, which in quantity would correspond to a good stool, and which according to the statement of the patient's husband, who in this case is to be absolutely relied upon, had just been vomited by the patient."

Dr. Kral had the opportunity to observe the patient vomit a small amount of formed feces in his own presence, and eventually introducing the stomach tube, he could for a long time draw off, through this, yellowish and fecal smelling water, together with solid pieces of feces. At this time the patient asserted that several years previously she had suffered from peritonitis, and her husband substantiated this information by reason of the opinion expressed by the physician who attended the woman at that time. This induced Dr. Kral, in consideration of the immediate symptoms to send the patient at once to our Clinic. She presented at her admission (June 26th, 1898) the following condition:

"The patient was somewhat collapsed, and appeared to be quite excited. Pulse 110, fairly strong, cheeks flushed, temperature 38°. Tongue moist. Singultus was present; facial expression anxious. The abdomen appeared to be slightly distended, and in the right lower abdominal region there was slight pain on pressure. But neither through percussion nor through palpation were there any definite signs by which to locate an obstruction. The same can be said of the rectum, which was empty. According to the patient, wind had not been passed for a long time."

The question was, should I operate or not? That this patient was a marked hysteric, I had already been informed; that therefore the fecal vomiting might be a hysterical symptoms only, I also knew. But on the other hand a mechanical obstruction could not be excluded. I thought at the time of a peritoneal band, and in that case the postponement of the operation could be of fatal significance. So I finally concluded to operate."

"Under morphine and chloroform narcosis an incision was made which extended from a point of 3 fingers breadth above the navel and reached to the symphysis. After opening the peritoneum intestinal coils of normal dimensions presented themselves. As no abnormal or mechanical obstruction was immediately evident, gradually and under the greatest caution a complete eversion of the intestines was made. Despite this fact there was, however, not the slightest sign of inflammation nor of mechanical obstruction revealed, nothing, in fact, which explained why fecal vomiting had occurred. Even a widening of the intestine at any point could not be detected. On the contrary, the small intestines, at several parts, which belonged to the lower part of the ileum, were found to be in stretches of 10 cm., narrowly contracted and hard to the feel. At several points little scybala, which were closely grasped by the intestines and were bounded above and below by contracted intestines, could be moved by pressure. At no place during the operation was one able to see the slightest suggestion of peristalsis. Mechanical irritation only produced a slow local contraction. At no place were there solid fecal masses nor any accumulation of such. The colon was everywhere soft, and its lumen distended to its normal dimensions.

"After the exploration, the abdomen was closed with exact reference to its layers."

"As soon as the patient was roused from her narcosis, I sought her out and showed myself very much satisfied over the operation just accomplished and told her that the obstruction was found and successfully removed, and that now she would be forever freed from her intestinal symptoms. The course of the wound after the operation was a good one. But the symptoms on the part of the intestinal glands gave us some further trouble; namely during the first ten days from time to time there was obstinate and colicky vomiting (not of a fecal nature), which was finally quieted by morphine. On the second day wind was expelled, but not until after the fifth day of the operation could she obtain stool by means of clysters; from that time forward, however, normal stools occurred."

"Frequently after this I saw the patient, and ½ a year later she reported that she had been several months pregnant, but that despite of this she was quite capable to work and attend to her household duties without experiencing the slightest inconvenience. Furthermore, that she had normal stools and was perfectly well in every other respect."

Wölfer's Case.—Some years ago Prof. Wölfer observed a similar case at the Grazer Clinic. In this case also on account of the symptoms of intestinal occlusion and because of the assertion that there was fecal vomiting, laparotomy was performed and a condition similar to that found in the case just reported revealed, and again in this case, although the results of positive examinations are not on hand, yet certain symptoms point conclusively to the fact that this case also was one of hysteria.

"Fanny Rotter, 31 years old, of Radkersburg in Steiermark, who was sent to the Grazer Clinic by Dr. Einfeldt; had been under medical treatment for a long time, in part, because of symptoms of peritonitis; in part, because of an anuria, occurring several times and lasting several days, and at that time made one think of hydro-nephrosis. Since then there have been frequent attacks of constipation lasting 11 days. When the patient came to our clinic in fact, just 14 days had gone by without the occurrence of stool. Recently the patient had suffered from vomiting and belching and finally fecal vomiting was supposed to have occurred. Severe pains in the abdomen which were localized near the middle of the central part of that region accompanied as a matter of fact by a not very marked meteoric distention; this together with the assertion that absolutely no wind had passed per rectum within the past few days, although during this period there was frequent belching, completed the picture of chronic intestinal occlusion."

"However, in the operation performed by Prof. Wölfer, November 10, 1888, no peritonitis nor obstruction was found, which would have prevented the evacuation of stool. The intestine was nowhere strikingly distended, only in certain places somewhat widened. The colon was everywhere filled with hard scybala and at several different parts the small intestine was contracted between two points, which latter corresponded to parts of the intestine whose lumen was filled with a scybala mass."

The course after the operation was a smooth one, and after a few days normal stools occurred. The patient went home after having been under observation clinically for five months. The stools were always sluggish and she frequently had to resort to laxatives. Something more than half a year after the operation the patient first observed a painful swelling of the abdomen in the region of the old operation. The pains became constantly worse; the swelling grew more prominent, it reddened and became inflamed, and one night, according to the patient, there was suddenly severe tenesmus, which only ameliorated towards morning when the inflamed swelling broke and a great evacuation of feces took place at that point. During the following days many hard fecal nodes came through this opening. From now on nearly all the stool evacuations took place at the artificial anus. In the summer of 1889 the patient again returned to the Clinic and at that time she had an intestinal prolapsus 15 to 20 cm. long, through the artificial anus, which was slightly incarcerated and which could only be replaced by the greatest of difficulty, after ice applications. On January 23d, 1893, Prof. Wölfer operated and closed the artificial anus. At that time an intestinal resection and suturing was done, and the patient made a good recovery. A few days after the operation the assistants attending the patient were frightened because she was found with a high degree of meteorism,

although her general condition was good. This meteorismus again disappeared and on the 4th of April the patient was discharged with a slight ligature-fistula in the scar, but having normal stools. According to the patient this fistula healed at home after which she was well for several months. Then, however, another little fistula formed which day by day secreted a little; then again under symptoms of fever, swelling occurred at the scar which after a time opened, and again there developed an artificial anus through which all stools emptied themselves. Since then nothing has changed in the patient's condition. She did not wish her artificial anus closed through which she had regular stools, but recently she has again manifested all manner of hysterical symptoms. I saw her again in the summer of 1898. Finally, it must be further mentioned that at one time the patient had a paralysis of one arm and a simultaneous circumscribed anesthesia of the thigh on the same side."

(11) **S. Talma's Case.** "K, 20 years old, belonging to the better class; hereditary nervousness; suffered repeatedly from severe attacks of colic, which weakened him very much. Of these attacks the following peculiarities may be reported:"

"The uncomfortable feeling in the abdomen, which he constantly suffered, gradually increased for a few days; the stool became very sluggish. The uncomfortable feeling increased until it became a pain; stool then became altogether inhibited. There arose a very uncomfortable feeling of cramp in the bladder and in the testes, and without ones being able to constitute any change in the position of these organs; the patient felt as if these organs were being drawn violently upwards."

"The abdomen in general was, without any contraction of the abdominal muscles themselves, very sunken. Towards the left side of the linea alba, however, in the hypogastrium the abdominal wall was in several places pressed upwards by two tumors, one of which was sausage-shaped, the other being in the shape of a ball. These tumors constantly changed their resistance without becoming altogether soft. They gave a tympanitic and fairly deep percussion note which during the greatest increase of resistance became less loud, higher and no longer tympanitic. Through the sausage shaped tumors there proceeded constant peristaltic movements. In short, they were intestinal coils (of the small intestine) whose contents were for the most part gaseous and which did not permit of either an upward or downward displacement. Intestinal colic could therefore be diagnosed with absolute certainty. That the contents were not displaced by the violent cramps of the intestinal wall, is proven, because at the end of the distended coil the intestinal lumen was closed by the cramps. That the cramps were the immediate cause of the pain was proven in that the latter increased or diminished according as to whether the former grew more or less severe. Under the feeling of a violent distension of the bladder there was frequently passed a small quantity of urine, which was rich in urates and free from albumen."

"Gastric cramps did not occur at this time."

"Pressure on the abdominal aorta above the navel caused violent pains; pressure on the ganglion beneath the navel was rendered impossible owing to the distended intestinal coils."

"In spite of the use of purges there was no stool. Fairly large doses of morphine injected subcutaneously did not dispel the pain. The stomach only tolerated small quantities of fluid nourishment."

"Through a large dose of antipyrine the intestinal colic as well as the colic of the bladder, and the feeling in the testes disappeared. Stool followed. Larger quantities of fluid nourishment could be taken. The patient's strength, which had greatly suffered, gradually increased; even after several weeks, however, he still felt very weak."

"Seven days after my first examination I was able to examine the patient again. He then was complaining of the same feeling in the abdomen and testes. I again found beneath the sunken abdominal wall a pair of distended fairly hard intestinal coils, which the patient said was the region of the pains. Besides this the parts in front of the abdominal aorta are very sensitive. The stool was again interrupted for two whole days."

"A large dose of antipyrine dispelled the pain at once. Quinine had, in the course of the following days when the symptoms of milder cramps presented themselves, an equally beneficial influence. Under the use of these reme-

dies and of easily digested food, at the same time keeping the abdomen well covered with thick woolen coverings, the intestinal cramps disappeared altogether, and gradually also, even if later, the uncomfortable feeling in the testes."

"During the months which followed under a similar treatment, the conditions became much better; at times antipyrine had to be given for the intestinal cramps, but frequently quinine was sufficient."

During the course of these months an attack of gastric cramp developed, which was accompanied by vomiting, etc. (I regard this fact as worthy of note in that it proves the cause of the gastric cramp and intestinal colic was one and the same.)"

"During this entire time the sympathetic remained, even if to a lesser degree, very tender to pressure, and upon pressure on the abdominal sympathetic the old and very uncomfortable feelings were manifested although less severely. Finally the neurosis of the sympathetic was so far cured that I could advise the patient to return to Dr. Metzger, who had already greatly benefited the ailment through abdominal massage."

(To be Continued.)

A NEW METHOD OF MAKING TANNIN AVAILABLE AS AN INTESTINAL ASTRINGENT.

By ALBERT C. BARNES, A.M., M.D., and H. HILLE, Ph.D.
of Philadelphia.

The great disadvantage attendant upon these remedies employed for astringent action upon the intestinal canal is that they are not only astringent to the stomach, but also undergo certain chemical changes in the gastric and intestinal juices whereby they are deprived of their astringent properties.

Pharmacologists well know that an agent designed for local action upon the intestines must be unaffected by the gastric juice, must be free from action upon the gastric mucous membrane, pass into the intestines chemically unchanged and must not be absorbed. It can be safely stated that not a single one of the intestinal astringents employed to-day possesses these desiderata.

The salts of the metals—silver, lead, copper—have so many objections that their application is exceedingly limited, and, in fact, meet few, if any, of the indications. Tannic acid is acknowledged to be the ideal astringent for mucous membranes if it can be brought chemically unchanged, in contact with them. This astringent action is due to the fact that tannin causes structural changes in the mucous membrane, whereby the albuminoid bodies are precipitated. There ensues, consequently, shrinking of the parts, constriction of the capillaries, and diminution of secretions. Heinz observed also that tannin causes a cessation of the movements of the leucocytes at the point of application and prevents their escape from the blood vessels, thus removing an important factor in the pathological condition of catarrhal inflammations and ulcerations. However, when tannic acid is administered internally, but a very small quantity reaches the intestines, because it is decomposed by the gastric juice into gallic and pyrogallie acids, which are non-astringent. Furthermore, the principal effects of the tannic acid consist of undesirable and deleterious actions upon the stomach, i. e., it coagulates the entire superficial layers of the gastric mucous membrane, thus practically abolishing the functions of secretion and digestion, and leads to grave functional and organic disturbances of the stomach. Because of the chemical changes which it undergoes in the presence of

the gastric juice, and because of its deleterious effects upon the stomach, the almost ideal astringent properties of tannic acid cannot be made available for the intestines.

Schmiedeberg, the highest authority on pharmacology, recommends that tannin-bearing plants (kino, catechu, krameria, etc.) be employed instead of tannic acid, because in these plants the tannin exists in combination with various gummy colloid materials, which, on account of their insolubility, prevent the rapid elimination of the tannin and thus, to a certain extent, diminish the local astringent action on the stomach. However, as is well known, even the tannin-bearing plants disturb the stomach, and, moreover, form an uncertain method of medication, inasmuch as the tannin exists in them in unknown and varying quantities.

Gottlieb, of Heidelberg, found that by precipitating albumin with tannic acid and then heating the resulting tannin albuminate for five or six hours at a temperature of 110°C ., this body could be made to a certain extent resistant to the action of gastric juice. Extensive reports particularly from the European clinics, prove that this tannin albuminate is a decided improvement in the previous methods of administering tannic acid. However, as is conceded, this tannin albuminate does not possess the properties of an ideal intestinal astringent. It was supposed by Gottlieb that this body being heated to the high temperature above noted, would render the albuminate digestible with difficulty and consequently the tannin would be first freed from its combination with the albumin when the compound reached the intestines. The following experiment shows that this is not the case: Two grammes of tannin albuminate were mixed with 100 cc. of water to which 0.2 gm. absolute hydrochloric acid and 0.2 gm. pepsin were added. This, as will be noted, corresponds exactly to the composition of the gastric juice. Digestion was then allowed to proceed for six hours at 40°C .—the temperature of the human body. The mixture was then filtered, dried and weighed, when it was found that 1.19 grammes, corresponding to sixty per cent. of the tannin albuminate had been digested and dissolved. This experiment was repeated four times always with the same results. It is therefore evident that a tannin containing body which dissolves to the extent of sixty per cent. in an artificial juice under exactly the same conditions as prevail in the human system cannot be considered free from astringent action upon the stomach.

Incidental to some pharmacological and chemical work upon the nucleo-proteid class of bodies the writers undertook to produce a tannin compound that would be even more resistant to digestion, consequently present more astringent tannic acid to the intestines, and what is even more desirable, but very gradually evolve free tannin from the compound when the body is acted upon by the alkaline intestinal juices. The object of the latter attribute is, in as much as in most cases of catarrh and ulceration of the intestines, the lesions are present also in the lower portions of the intestines, the astringent action of tannin upon these parts of the canal is very desirable. The writers found that by the synthesis of nucleinic acid and albumin there results an entire-

ly new body which chemical analysis shows belongs to the nucleo-proteid class of bodies. Under certain chemical and physical conditions this body enters into combination with tannin and forms a yellowish-brown, tasteless powder containing fifty per cent. of tannic acid. This tannic nucleo-proteid is insoluble, does not precipitate albumin, pepsin or peptones. We instituted the same experiments as made with tannin albuminate and secured the following results: Two grammes of tannin nucleo-proteid, 100 cc. of water, 0.2 grms. absolute hydrochloric acid, 0.2 grms. pepsin were digested for six hours at a temperature of 40°C . It yielded but 0.5 grms. in solution; that is seventy-five per cent. of the body retained its original form. Even forty-eight hours' digestion under the same conditions failed to further digest the body; it is therefore evident that seventy-five per cent. of the tannin nucleo-proteid passes through the pylorus chemically unchanged and the body must be therefore practically free from astringent action upon the stomach. The following experiments show the behavior of the tannin nucleo-proteid toward the alkaline intestinal juices. Two grammes of tannin nucleo-proteid were digested 6 hours at 40°C . in an artificial pancreatic juice consisting of 0.1 gm. pancreatin and 0.33 grms. sodium carbonate. There went into solution 0.56 grammes (twenty-eight per cent.) of the body; 1.44 grammes remained unchanged. Further experiments showed that it required additional alkali to dissolve more of the tannin nucleo-proteid. These experiments demonstrate that this tannin nucleo-proteid *but very gradually evolves tannin from its combination*.

The advantage of this gradual elimination of tannin from tannin nucleo-proteid can be readily understood. As the remedy passes downward through the intestines and meets fresh portions of the alkaline juices, more and more tannin is gradually released. Thus is the astringent brought into contact with the entire intestinal canal, even to the lowermost portions of the colon, as is evidenced by the fact that small quantities of tannin nucleo-proteid and tannic acid may be detected in the feces.

Another advantage of this gradual elimination of tannic acid from tannin nucleo-proteid is that the astringent action of tannin is more complete when but small quantities come in contact with any one portion of the intestinal mucous membrane, while large quantities produce local irritation and defeat the objects of treatment. (Schmiedeberg).

In order to determine the effect of the tannin nucleo-proteid on animals it was tried on fifty calves which had been fed exclusively on milk and were suffering from profuse diarrhea. As every veterinarian knows this form of diarrhea is one of the most intractable. Four grammes of tannin nucleo-proteid were administered at intervals of from two to three hours. In most cases the diarrhea ceased at the end of forty-eight hours; at the end of four days the epidemic was completely controlled. Clinical trials on human beings in two Philadelphia hospitals and in one New York hospital, now being conducted, indicate that tannin nucleo-proteid will be a valuable adjunct in the treatment of various diseases of the intestines associated with diarrhea.

SOME OBSERVATIONS RESPECTING THE VALUE OF THE PRESENT METHODS OF MEDICAL EDUCATION.*

By AUGUSTUS P. CLARKE, A. M., M. D.,
of Cambridge, Mass.

Dean and Professor of Gynecology and Abdominal Surgery in the College
of Physicians and Surgeons, Boston, Mass.

The changes introduced during the past few years into the system of medical education have been most marked and have become themes for important discussion. The old method of the students having the instruction or direction of a preceptor, has been largely displaced by more extended college courses. This has been rendered necessary by the large numbers of students who have of late years entered upon the study of medicine and presumably for the reason that there has arisen a greater difficulty than there was formerly in securing outside instructors who are inclined to take students, owing to the sharpness of competition and to the manufacturer's ability to present for general use numberless varieties of remedial agents. The régime to which the medical student was subjected was undoubtedly a great help and the experience of that service tended to make him familiar with the uses and advantages of most of the medicines on which the physician could place his main reliance and upon which the success of his practice generally largely depended. The multiplicity of courses and the division of labor on the part of the teaching force have not unfrequently served through the disposition of a professor to emphasize his own individual department and to change the whole aspect of affairs. The average student realizing the impossibility of thoroughly mastering within the short period of four years all the various subjects that are continually being placed before him finds that he must sharpen his wit and must resort to many expedients. The materia medica which by some state boards receive but small attention is passed over with as little consideration as is possible by the graduating student. The real lack of understanding of this portion of medical science has been the cause why numerous proprietary articles have been substituted for those which should have been studied and prescribed with greater care. If the student has a fair or practical acquaintance with the English or with the language in which he is to be examined, he soon learns the art of speaking or writing in platitudes and of arranging indefinite statements as a substitute for exact and perfect answers. The hobbies and pet theories of individual professors or instructors have to be studied or more or less considered; a partial comprehension of these may serve as a substitute for the real marks of scholarship. The sharpening of the wit and the calling out of latent talents or the devising of expedients may be regarded by some as the result of educating influences, and perhaps to a certain extent such attainment may be most helpful in the subsequent management of trying cases, but the value of such methods of doing falls far short of the object to which the student at first intended to direct his energies. It must be admitted, nevertheless, that there has been upon the whole within the past few years a great advance made over the older methods of medical training. One of the chief drawbacks

which still exists to the higher attainments lies in the need of the right kind of preliminary education. The student coming from what is often termed a first-class college from which he has obtained the A. B. or the B. S., or other equivalent degree, is often in reality no better suited to enter and to follow out the exactions of the medical profession than are those who have spent much less time in preliminary acquirements. Take into consideration, for example, the ordeal through which in this vicinity the student has to pass before attaining his first degree. Three years in the primary school, six years in the grammar school, and five years in the Latin school and then four years in the college, thus making eighteen years spent, and for what? why, simply, it may be, to become prepared to enter upon the study of the mere rudiments of medical science. I shall never forget the remark once made to me by my friend, the late Dr. Samuel Nelson, who said that after having successfully passed through a similar ordeal subsequently graduated at the Harvard Medical School and then spent two years in Germany; that in endeavoring to fit himself for doing good work he had seriously impaired his health in consequence of the prolonged period of overwork, and that on the completion of his preparation, the woods he found were full of competitors. Thus twenty-four years had been spent before he was regarded as ever competent to commence his life service at the foot of the ladder. What would seem now to be imperatively demanded would be the establishing of proper courses for medical students, courses that while duly fitting the student to enter upon the successful study of medicine, would admit of more expedition, would be more conservative of his energies, courses that would have an alluring influence, that would lead him along, and that would beget in him the true spirit of scientific investigation and, above all, afford the opportunity of allowing him to engage earlier in the more direct work to be carried on during his life, and one that would be so complete and conservative as to offer no temptation to be indulged in whereby his ardor and assiduity in the pursuit of the more strictly professional part of his curriculum would be lessened. In such a course a considerable portion of time should be given to the acquirement of French, German, or other modern languages. Half of the delights of professional training are not realized, owing, as it is too often the case, by the failure to be acquainted with those languages. Too much time is often worse than wasted by the student's endeavor to gain a mastery (but only of the rudiments) of ancient tongues. Such a study is better adapted (if one wishes to have only ancient ideas of philosophy) for theologians, antiquarians, or men of leisure. Some academic colleges, notably Harvard, have recently allowed the first successful year in its Medical School to count as the final year toward the A. B. degree; but this, it is plain, is only a temporary expedient to be employed until a more specific and conservative course can be adopted. I think the time has fully come when no allowance for any of the four years' course should be made on account of the students' possession of the A. B. or B. S. degree. If the student is unwilling to devote the full four years to the study of medicine before receiving the medical degree, he had better take up some other

*Presented to the Section on Pedagogy of the Third Pan-American Medical Congress, held in Havana, Cuba, February 4-7, 1901.

calling. It would be preferable to have the time extended to five or six years instead of its being lessened on account of the possession of any attainment whatever. As regards the question of the success of coeducational institutions in medicine, there can be but one opinion; such schools should be encouraged. They have a reforming and an educating influence on the men and even on the professors; they tend to improve their manners, fit them for society, and to keep down their conceit. The women often show the men that they are able to become competitors who may outdo them in the race. Much of late has been said of the great advantages of the laboratory and of the case system over those of the purely didactic method of teaching. Any and all of the different methods have their operation of usefulness. The time is far distant when didactic courses can safely be dispensed with. The teacher "flaming with enthusiasm," bringing all the years of his ripe experience into culling from the heterogeneous mass the real or vital facts to be remembered will always be held in high favor. No dissecting room, no laboratory, and no case system, can be wholly substituted for the inimitable descriptions that were sometimes given in lectures by Oliver Wendell Holmes, for the bold spirit that was so often displayed by Henry Jacob Bigelow, for the enthusiasm shown in recounting the original investigations made by Virchow or for the eloquence and beauty of statement presented by Lannelongue. When making a demonstration before a class or delivering a lecture, I have always insisted upon the compliance with the rule that the members should take notes so that they could afterwards read up and be able to recall in detail what had been brought before them. In speaking of the value of didactic lectures to students and of the importance of their learning the contents of text-books, it deserves to be remarked that time employed in that direction is always exceedingly useful. The advantages thus accruing may be aptly compared to the careful preparation that should be made by the tourist or traveller before taking his departure for a foreign country. Those who usually have made the best attempts to learn the language of the country to be visited and to inform themselves upon the nature and character of the scenes and objects to be met with, have profited most by taking such a journey. All experience in such travels proves the truth of this statement. The same obtains with the student before as well as during his entrance upon his laboratory work, upon the courses of his dissections, and upon those at the bedside. One great fault in the text-books which are prescribed is that they are often ill-adapted for the student's need; such books are all too often compiled and put forward more for the interest of the publisher and for the advancement of the author than for meeting the real needs of the students. Hence, the greater value of a lecture course given by an experienced teacher. Free drawing and illustration upon the blackboard become a more or less important means of enhancing the value of a lecture. Such illustrations not infrequently prove to be much better than are printed charts hung up before the class. The professor's diagrams tend to excite interest and to stimulate the members at trials of their own skill in this direction. No one can doubt the advantages to be

derived from devotion to laboratory courses; here it should be remarked that a large part of the whole four years' course should be employed in the laboratory, in the dissection, and the autopsy rooms, at the bedside of the hospital or in the dispensary under the supervision of competent instructors. No student should receive the degree of doctor of medicine until he has attended at least six successful cases of obstetrics and has been made to feel that he has had to share with his instructor a part of the responsibility of the work. The course in gynecology and abdominal surgery should be well illustrated; its lessons should serve to impress upon the student the dangers resulting from the neglect to take proper precautions against sepsis and the dangers of allowing any accidents occurring through traumatism of parturition to go unattended to. Careful drilling and frequent examination upon all important subjects should be insisted upon. The student should be required to do much original work in the way of examination and in the diagnosis of disease. He should be able to present a good paper, exemplifying a genuine scientific mode of observing facts and a ready yet rational method of making a deduction. Such a paper should be expected at intervals until the time for the preparation of his final thesis; the appearance of the latter should be judged as to the student's full ability to recognize and to interpret many of the more obscure and varying phases of diseases. The standing of every student should be known to the professor not only by record, but also by being reinforced by much personal observation as to his habits and manner of pursuing his work. I believe that the custom obtained of passing judgment upon answers to written questions without knowing anything personally as to who the candidate may be, is an unwise measure of proceeding. The practice savors too much of the expedients of the politician, who, for the most part, is anxious to offend no one if he can merely gain his ends. If the student is unsuccessful in examination, I believe that it is far better to tell him plainly in what his deficiency consists, that he may profit in due time by the lessons of such bitter experience. Before closing, allow me to say that a medical school should not assume so much of the task of completely fitting the student before graduating to become a specialist in all of the various branches of medical science as it should be to urge upon him the necessity of becoming well grounded in all of the essential principles underlying the healing art. The accomplishment of the specialist can only be gained by much post graduate work and by frequent contact with experts of the individual line to be pursued.

A Case of Poisoning from Russet Shoe Polish.—In the *Journal des Sciences Médicales de Lille*, 1901, No. 29) Adrien Besson reports a case of poisoning, in a child of 6 years, from russet shoe polish containing anilin. At noon, after having played upon the sea shore all morning, she came in pale, though with a good appetite. Cyanosis and torpor gradually came on. Her mother quickly put her to bed, noticing how blue and cold her extremities were. By three o'clock she was quite blue and cyanosed. Heat and stimulants cured her in a day. She had, however, worn new shoes, polished with russet shoe polish. They had a distinctly nauseating odor. Since that time she has kept well. The shoes were never worn again. Analysis of the shoe polish showed 91% pure anilin. [M. O.]

A FEW INTERESTING OBSTETRICAL EXPERIENCES.*

By J. THOMPSON SCHELL, M. D.,

of Philadelphia

Gynecologist and Obstetrician to the Prince of Peace Hospital; Demonstrator of Obstetrics Medico-Chirurgical College, Gynecologist to the Out-Patient Department of Samaritan Hospital, etc.

Mr. President and Gentlemen:

The title of this brief communication may be poorly chosen, as it possibly is presumptive on my part to style the following cases interesting, but such they have been to me as well as instructive, and it is with the hope they will prove equally so to you that I now ask your kind indulgence for a short time.

The first three cases resemble each other in many ways and seem to me to teach several important lessons. They are as follows:

CASE I.—Mrs. F., white, aged 33, married 12 years, had one child at full term during the second year of her married life, a miscarriage at 6 months 2 years after the birth of this child, and another miscarriage 2 and a half years later. Her menstrual history is as follows: puberty at 12 years, always regular and painless at intervals of 28 days and with normal flow lasting from 4 to 5 days. For the 2 years preceding the history of her present trouble she complained of backache, more or less severe, some leucorrhea and pain in the lower part of the abdomen, especially in the left iliac region. Menstruation became more profuse, with considerable pain, on the first day but not enough to require medication.

Her present trouble dates from November, 1898, when she had her last regular period. The December period failed to come on and at that time she became nauseated with some vomiting in the morning. Frequent urination and feeling of weight and gradual enlargement of the abdomen were noticed. The nausea gradually diminished and disappeared about February 1st. On the 28th of March, 1899, she felt what she believed to be fetal movements, which persisted constantly and distinctly until she fell in labor, August 13th, 1899. Up to this time she was in the hands of a neighboring physician, who was called to deliver her. After laboring 18 hours she became exhausted and discouraged and, discharging her physician, called in another, who sent her to the Samaritan Hospital, where, in the absence of Dr. Haehnlen, through whose courtesy I report this case, I was called to deliver her. On questioning her at this time a part of the above history was elicited and, in addition, she informed me that a large quantity of water had come from her about 10 hours after she noticed her first pain. On examination I found a stout, well built woman, weighing about 190 pounds, with a tremendously enlarged abdomen, striae and linea niger very faintly shown, the breasts contained colostrum and the primary and secondary areola were present.

Bi-manual examination elicited a soft, club shaped cervix, lacerated bilaterally and patulous to the internal os, which was tightly closed. No distinct uterine enlargement could be made out on account of the thick abdominal walls nor could any fetal movement be felt or fetal heart sounds or uterine souffle be heard. On examination under ether, the uterus was felt enlarged to about the size of a 2 months pregnancy. In a normal position, the left ovary was enlarged and the whole left broad ligament, including the tube, was thickened. There was a muco-purulent discharge from the uterus and a curettage was done, with no other results than the removal of some shreds of endometrium, and a diagnosis of complete pseudocyesis was made, with ovarian disease as a positive cause. Subsequent history: Patient was discharged 12 days later from the Hospital with abdomen as large as on admission. Periods have been regular ever since with some pain on first and second day, backache and a soreness or tenderness in the left iliac region; otherwise her condition is normal.

The lessons that are taught by these cases are: (1) that

pseudocyesis, or any of the so-called phantom tumors of the abdomen, can only be diagnosed correctly by a careful examination under an anesthetic, and; (2) that the ovarian disease present in these cases had in all probability a casual relation to the symptoms related. The literature on the subject, however, is very barren, and I could find no reference to any relation between pelvic diseases and pseudocyesis, which I am inclined to think my three cases seem at least to suggest.

CASE II.—Mrs. H., a markedly neurotic patient, aged 33, married 11 years, had two children, followed 3 years ago by a miscarriage. Puberty occurred at about 13 years and has since been irregular but not painful. On October 1st, 1899, I was requested by her physician, Dr. W. H. Hornby, to meet him in consultation to assist in making a diagnosis. The history is briefly as follows: Had amenorrhea extending over January, February and March, with nausea and some vomiting in the morning. The abdomen during these three months was noticed to be steadily enlarging. She was examined at this time by another physician who pronounced her 4 months pregnant, and he was engaged to deliver her, the nurse being also engaged at this time. In April she began to menstruate again and had what was apparently normal periods in May and June. The abdomen, notwithstanding the menstruation, seemed to be getting steadily larger, and in July nausea reappeared but menstruation failed to come on at this time. Dr. Hornby was called and expressed doubts as to her being pregnant. The breasts at this time were enlarged, veins were markedly distended and colostrum in abundance was present, with a distinct primary and secondary areola. In August and September she had metrorrhagia and menorrhagia. When I saw her on October 1st, 1899, the abdomen was enlarged to about the size of a full term pregnancy but no fetal heart sounds or uterine souffle could be heard. I suggested an examination under ether with the following results: The uterus was slightly enlarged and retro-displaced, both ovaries prolapsed, tubes apparently normal as to size and the right ovary quite considerably enlarged. A curettage was done and the patient made a good recovery. Subsequent history, which was kindly furnished by Dr. Hornby, is as follows: Since the recovery from the curettage Mrs. H. has been under my care at different times for her general nervous condition and she had some nausea and backache. Her abdominal enlargement disappeared, her breasts regained their normal size, and she lost considerably in weight. At this time she has missed two periods and has had morning sickness and frequent micturition with slight enlargement of the abdomen.

CASE III.—Mrs. D., age 30, married 3 years, had a miscarriage during the first year of her married life, had not been pregnant since and was very anxious to become a mother. Puberty occurred at 14 years, and was regular and painful. If compelled to be on her feet a great deal, the pain with the next period would be considerably increased. Had always had leucorrhea and backache as long as she could remember. Periods were regular after her miscarriage until November 10th, 1899, and from that time she had amenorrhea extending over December, January, and February. About the middle of February she thought she felt life, which was noticed until March 10th, 1900, when she started to menstruate again. At that time I was invited by Dr. Kline Baker, her physician, to see her, and advised an examination under ether, with the following results: The uterus was normal as to size but slightly drawn to the right side, the left ovary and tube were markedly enlarged and the right ovary was apparently normal, with a slight muco-purulent discharge from the uterus.

Subsequent history: Menstruated normally each month for 5 months and then missed one period with some morning nausea, but from her previous experience did not think she was pregnant and reported to her physician, who finding evidence of some congestion of kidneys prescribed a diuretic, three days after which menstruation came on and it has been regular ever since up to the present time.

CASE IV.—The following case is reported because it illustrates so well one of the causes of the mal-presentation of the head. I was engaged to deliver Mrs. H., a primipara, aged 26, and, following my usual custom, made a careful

*Read before the North-West Medical Society, November, 1900.

examination, including pelvic measurements. The examination revealed a small woman, with slight scoliosis, pelvic measurement between the anterior superior spines, 25 cm., crests 27 cm. and of Baudelocques', 19 cm. Vaginal examination: head presenting at superior, straight and very high up, and back of fetus to the right and the posterior fetal heart sounds were most distinctly heard to right and posterior part of the abdomen. No abnormality of pelvis could be made out. I calculated her time to be about May 25th, and did not see her again until she fell in labor, June 2nd, 1898. Vaginal examination at this time revealed the head high up and floating at the brim, the cervix was tightly closed and the pains irregular and not severe. I instructed her to send for me when the pains increased in force and frequency, and two days later I received a message to call. On reaching the patient I found the cervix dilated to the size of a silver dollar, and the bag of water bulging well into the vagina, the presenting part still in the same position as previously mentioned. On careful examination I was able to make out the features, with the chin pointing posteriorly, and I then did a podalic version. The patient was delivered safely and made an uninterrupted recovery. I was engaged again later to deliver her of a second child which was due about December 25th, 1899, and when I made the usual examination I found the same condition as existed in the previous pregnancy, viz: a right mento-posterior position. I left instructions that I should be sent for as soon as labor started, but this was not done and she suffered 24 hours before I was called, as she wished to avoid the etherization. On examination I found the face presenting and still high up at the brim, the os dilated, the bag of water unruptured and, under ether, I did podalic version and delivered without any trouble. After the child was delivered and while the patient was still under the anesthetic, I made a careful examination and found what I consider to be the cause of her two mal-presentations, viz, a quite well-marked bony obstruction at the right posterior portion of the superior straight. The head probably presented as an ordinary L. O. A. in the beginning but the bony obstruction brought about an extension instead of a flexion.

CASE V.—This is the last and briefest case that I have to report. Mrs. E. B., age 41 years, has had 7 children, the first 20 years ago and the last one October, 1900. All her labors were normal. During the fourth pregnancy her face and arms became covered with the so-called chloasma uterinum, of a marked character, which has persisted, as

is also shown in photograph (Fig 1b). I have made a brief mention of this case because the chloasma is so well marked and has persisted so long, the usual rule being to disappear shortly after delivery. In addition to this, the location of this pigmentation will disprove the state-

Figure 1 (b) Chloasma uterinum on the buttocks and thighs.

ment made by Joul that chloasma uterinum only appears on portions of the body exposed to the sun, principally the face. I wish to thank Dr. Haehnlen for permission to report this case, and Dr. Brinkerhoff, Resident Physician at the Samaritan, for notes of the same.

PHOTO-MECHANICAL REPRODUCTION.

By B. H. BUXTON, M. D.,

of New York.

Instructor in Bacteriology, Cornell Medical College, New York.

(Continued from Page 80.)

THEORY

Of Collotype, or Alberttype or Heliotype.

Gelatine, which is soluble in hot water, absorbs cold water and swells up, retaining the moisture for a considerable period of time. Bichromatized gelatine acted upon by light becomes insoluble in hot water and no longer absorbs cold water. If a bichromatized gelatine surface is partly acted upon by light and partly not, the excess of bichromates washed out and the surface dried, it is no longer sensitive to light. On damping the surface, the unaffected parts will absorb moisture and swell up, whilst the affected parts will not, so can be easily dried out, and will take a fatty ink, whilst this will be repelled by the moist parts.

This is the theory on which the practice of collotype is based, but where homogeneous half tones are to be reproduced these must be broken up into minute dots or lines, or their modulations will be lost. Unless this is done the surface will either take ink or will not take it, and the resulting print will appear simply black and white. A grain, therefore, must be produced on the surface, and this might be done by using a negative taken through a screen, as for printing in relief, but there would be no advantage in this, since relief printing is much cheaper than surface printing, and with the coarse grain of the screen the latter would yield no better results than the former. A method, however, is known by

Figure 1 (a) Chloasma uterinum on the face.

is shown in photograph (Fig 1a), up to the present time. During her last pregnancy, which has just been completed, she noticed that a new area of chloasma appeared, which

which an exceedingly fine grain can be obtained on the gelatine surface itself; a natural grain, as opposed to the much coarser mechanical grain afforded by the screen. In order to produce this grain it is necessary for the gelatine to rest upon a surface to which it will adhere very closely, and for this purpose a ground glass plate with a thin covering of potassium silicate and albumen is used. Over this the bichromatised gelatine is poured and allowed to dry. Now if the gelatine is dried at ordinary temperatures it will set and then gradually dry out evenly all over, so that no grain will be produced. If, however, it is dried at a temperature of 130° F. to 140° F., at which it remains fluid in the presence of water, the upper layers will shrink in drying whilst the lowest layer will be prevented from doing so by the substratum to which it adheres. Diagrammatically the process may be thus represented::

Diagram VIII.

This uneven drying causes the surface of the gelatine to wrinkle up, and after drying it will present a matt surface. In other words, the surface is grained, consisting of innumerable minute points which are acted upon by the light during exposure. When the surface is damped after exposure the unaltered gelatine swells, pushing up the points and separating them more or less according as the action of the light has been less or more intense. These points take the ink, the moist gelatine between them repelling it. The points being exceedingly minute the half tones in the print appear as homogeneous to the unaided eye as those in a silver print, but a pocket lens resolves the grain, very fine in the high lights, but becoming coarser and coarser through the half tones towards the shadows.

PRACTICE

of Collotype.

The glass must be of patent plate, $\frac{3}{8}$ inch thick, so that it will stand the considerable pressure of the printing frame and press. The surface is ground with fine emery powder passed through a sieve of 130 to 150 lines to the inch.

The substratum is then flowed over and the plate allowed to dry, set up on edge in a rack. A formula for the substratum is:

Beer	10 oz.
Potassium silicate	1 oz.
Tannin	$\frac{1}{2}$ grain.

The potassium silicate and albumen of the beer cause the lower layers of the gelatine to adhere closely, whilst the tannin exerts a slight hardening influence, but not enough to affect the upper layers on which the light is to act.

A plate thus prepared will keep indefinitely, but just before using—or storing—must be washed for a few seconds to get rid of silicate crystals which may have formed on the surface. It is air dried, then placed in a drying box, levelled and warmed

to about 120° F. Of the drying box it is sufficient to say that it must be light-tight, and capable of being kept at an even temperature by a gas or other burner underneath. Inside the box bars with levelling screws are laid across and the plate rests on the screws.

Coating with Gelatine.

A formula for this is:

Hard gelatine	100 grains.
Soft gelatine	100 grains.
Water	$2\frac{1}{2}$ oz.
Potassium bichromate	50 grains.

Dissolve the gelatine and bichromate in hot water and filter, keeping the solution at about 120° F. Take the warm plate out of the drying box, place on a suitable leveller, and pour the solution carefully all over it, allowing 4 minims to the square inch of surface. If a plate 10 in. by 12 in. = 120 square inches is used, it requires 480 minims, or one ounce of the solution. If there is too much gelatine on the plate the grain will be too coarse, and if too little the grain will be too fine.

After coating, the plate is kept on the leveller in the drying box at 130° F. for about two hours and can then be taken out and stored in a light-tight box at ordinary temperature. Plates so prepared will keep for about a week, but it is best to use them as soon as possible.

Exposure.

For printing on the gelatine surface any negative may be used, a soft rather than a brilliant one being preferred, but it is not safe to use a negative on ordinary glass, as this is liable to break under pressure in the printing frame. Such negatives should be stripped and transferred to celluloid films or thick plate glass. Exposure is conducted in the shade, time usually about an hour, or in sunlight, in frames so constructed that the progress of the printing can be observed from the back: the shadows and deeper half tones of the picture gradually assuming a rich brown hue, due to chromic and chromous oxides.

On taking the plate from the printing frame, it is laid face downwards on a sheet of white paper, and the experienced eye can now tell if the exposure has been correct or not: the shadows showing as a dark brown. The unaltered bichromates and other soluble substances are now washed out in several changes of water until the brown color has completely disappeared. The plate is then insensitive to light and when dry is ready for etching.

Etching.—The plate is damped in order to cause the unaltered gelatine to swell. This is called etching, although, of course, it has nothing in common with true etching or biting in. The plate is levelled and flooded with water, which is left on for 5 to 10 minutes, then poured off and a mixture of two parts glycerine to one part water, called the weak etch, poured over and allowed to act for about 15 minutes: the glycerine preventing the gelatine from drying out whilst the printing is going on. The etch is then wiped off with a sponge and the surface of the plate dabbed over with a soft linen cloth, after which it is ready for the printing press. If the plate is over exposed it may be treated with a strong etch: the usual etch with a little ammonia added, which helps to soften the film.

In both of the preceding processes it is evident

that the final print will be reversed from the original, as its position in the cycle corresponds to that of a negative, and this must be overcome, if necessary, by reversing the negative. There are many ways of doing this, but as in ninety-nine times out of a hundred it is a matter of indifference to the photomicrographer if his pictures are reversed or not, the methods need not be considered here.

III.—Deep or Intaglio Printing. Photogravure. Theory.

In this process bichromatised gelatine is used on a copper plate to which, by means of powdered asphaltum, a very fine grain is given, and which is then exposed under a transparency and etched with ferric chloride. On account of the fineness of the grain, printing cannot be done in relief, as the ink would smear all over the surface of the impression. Recourse must, therefore, be had to deep printing: the ink is dabbed all over, filling up the hollows, and is then wiped off the surface of the grain points, so that these appear white, whilst the paper takes up the ink from the hollows. A fine grain is necessary for deep printing, or, on wiping over the surface, the ink would be taken up from the shallower hollows, and these would appear white on the print, although they ought to represent the lighter half-tones of the picture. With a fine grain, however, the ink simply wipes off from the points, and the modulations from shadows to high lights depend more upon the number and fineness of these points than upon the actual depth of the hollows. As the printing is effected by taking up the ink from the hollows, it is evident that the etched out part will represent the shadows, and the gelatine in these parts must be unaltered during exposure, so that it can be washed away. Exposure is, therefore, to be conducted under a transparency instead of the negative, which is used for relief or surface printing.

Practice.

The final print will be reversed so a reversed transparency may be needed. The negative can be reversed, and from this a transparency made on a gelatine emulsion plate in the camera, or the transparency may be made direct from the negative by the carbon process, by which method, since development proceeds from the back, reversion is accomplished.

As few amateur photographers are familiar with the carbon process, it will be well to describe it so far as it applies to making transparencies, especially as development on the copper plate is done in the same way, so that one description will do for both. Stuff paper is coated with gelatine mixed with some colored permanent pigment and dried. This is called carbon tissue, and may be sensitized by immersion in a solution of potassium or ammonium bichromate and then drying in the dark room.

The tissue is exposed under the negative in an ordinary printing frame, and since the progress of printing cannot be watched as with a silver print, the brown tints observable in the collotype process being obscured by the pigment, it is customary to use an actinometer to assist one's judgment as to the proper length of exposure. The tissue prints

in about one-third of the time required for a silver print.

A glass plate somewhat larger than the piece of tissue is laid in a dish of cold water, into which also the tissue is plunged immediately after exposure. At first the tissue curls up, but flattens out as soon as it is moistened throughout, and must then at once be laid on the glass plate face downwards, and withdrawn from the water. Under a rubber cloth it is squeegeed tight to the plate, considerable pressure being used, and then kept for 20 minutes under pressure between sheets of blotting paper. It is then transferred to a dish of hot water at about 110° F. to dissolve out the unaltered gelatine. In two or three minutes the gelatine is sufficiently softened to enable the paper backing to be stripped off and development is proceeded with by washing off the soluble gelatine, whilst the parts rendered insoluble by the action of the light, together with their contained pigment, by means of which the picture is rendered visible, remain adhering to the glass plate, which is washed in cold water and allowed to dry.

From the transparency a negative is then taken on what is called the resist. The resist is also a carbon tissue prepared and sensitized practically in the same way as the ordinary tissue, except that the presence in it of so much pigment is not essential. Enough of this to enable the progress of development to be seen is all that is necessary.

The procedures of exposure and development are the same as in the case of the transparency, except that a copper instead of a glass plate is used, on which to squeegee the tissue.

The copper plate, however, must be previously grained, and for this purpose some powdered asphaltum is placed in a revolving box mounted on trunnions. The box is rapidly revolved to fill the interior with a cloud of dust. The plate is then inserted quickly and the dust allowed to settle on it. On removing the plate it is heated over a Bunsen burner until the fawn-colored deposit of asphaltum changes to a slaty gray. On cooling the resist can be squeegeed on.

Etching.—For this solutions of ferric chloride of varying strengths are used: the weaker the solution within certain limits, the greater its power of penetrating the film and attacking the copper beneath. Etching is, therefore, begun with a strong solution to penetrate the thinner parts of the film first, and is gradually weakened as etching proceeds, so that the thicker parts of the film may be attacked in regular gradation. By this means the shadows and deeper half tones get comparatively more etching than they would if a single solution were used, and stronger contrasts are obtained in the final prints.

Printing can only be done in a hand press, and not more than about 50 impressions can be turned out in a day, so that the use of this process is usually confined to reproductions of works of art for framing or for illustrating "éditions de luxe," but for general illustrative purposes the expense is too great, although the results are certainly superior to those arrived at by either the collotype or half-tone screen processes.

A photogravure can be distinguished by its plate mark. The paper is damped and printed under

great pressure, so that the bevelled edge of the copper plate leaves a distinct impression just beyond the margin of the picture. Here, however, a little knowledge is a dangerous thing, since a plate mark is often intentionally added to a collotype print in order to deceive the unwary and induce him to buy for ten dollars what is in reality only worth one or two.

Tri-Chromatic Photography.

A susceptible artist on seeing a tri-chromatic photograph is apt to shudder and refuse nourishment for some hours afterwards, but although we must agree with him that the results are crude and startling rather than artistic, and conclude that the photomicrographer is not likely to mar his work by this method of reproduction, still the theory on which the process is based is correct and of so much interest to the scientific mind, that a short account of it may, perhaps, be permitted.

The three primary colors of the spectrum, red, green and violet, when combined, excite three dis-

paper, for in this case all three sets of nerves have been rendered inert. This may seem to be a digression, but it is necessary to have a clear idea of the theory of complementary colors in order to appreciate the principles of tri-chromatic photography.

In the reproduction of colors, three negatives of the subject are taken: one through a red, another through a green, and the third through a violet-colored glass screen. In each case the color must be spectrum pure.

In the first case only red rays can pass through to the sensitive plate, so that on development silver will only be deposited where there are red rays, either pure or mixed with other colors emanating from the subject. With the green or violet screens, the green or violet rays would alone affect the plate; all others being cut off by the screen. The three negatives, from each one of which a metal plate is etched, may be represented spectroscopically by the following diagram, the printing being done from each plate in the complementary color:

Diagram IX.

tinet sets of nerves of the eye and give the impression of a white light of extreme brightness. Any two of these combined excite two sets of nerves and appear brighter than any one of them which only excites one set of nerves. These double colors are:

Blue or Violet + Green — Red.
Crimson or Red + Violet — Green.
Yellow or Green + Red — Violet.

and each of these colors is complimentary to the primary color which is missing in it, whilst the missing color is complimentary to it. This may be readily appreciated by staring at a colored disc for some moments and then looking at a sheet of white paper, when the complementary color will be seen. If, for instance, this disc be crimson, a green disc will be seen on the paper. The reason for this is that the two sets of nerves for red and violet have been excited to their limits, and are for the moment inert; the set of nerves for green being alone able to register any sensation of light. If the disc be white on a black ground, it will appear black on the white

The impressions are taken first with yellow ink from Plate 3, next with crimson ink from Plate 2 and finally with blue ink from Plate 1: exact superposition of red on yellow and blue on the first two being necessary. This order is always followed for reasons which need not be entered into here.

Now let us suppose green to be the color in a certain part of the picture, the rays from which would only impress upon the negative taken through the green screen, so that on the plate taken from this negative they would be etched deeply and would take no crimson, so that none would appear on the final impression. On the other two plates, however, they would stand out in relief, and the impression would take yellow, and over this blue. Now a yellow surface absorbs violet and reflects red and green, whilst blue absorbs red and reflects green and violet. Consequently, with blue + yellow, both red and violet are absorbed and green alone is reflected. The green of the original appears, therefore, as green in the print.

To take a double color, let us suppose crimson is to be reproduced, or red and violet. Crimson, therefore, will act on the negatives taken through red and violet screens, but not on the one taken through green. Crimson then remains in relief on the plate etched from negative No. 2 taken through the green screen, and is etched away in the other two. But Plate 2 is used with a crimson ink, and therefore crimson in the original appears as crimson in the print.

The rationale for the reproduction of any color can be worked out in a similar manner, but of course with the more complex colors, like pinks, purples, and lavenders, is not by any means so easy, though they can all be produced by varying proportions of the three printing colors. The theory certainly is beautiful, but the results are vile, partly owing to the difficulty of getting perfect colors for printing. It is impossible, for instance, to get a blue ink which will reflect *all* the violet and green rays and absorb *all* the red, but any deviation from this ideal will result in more or less imperfect rendering of the original colors, and the same applies to the crimson and yellow inks.

Another reason is that, in order to preserve the half tones of the original, they must be grained by the screen or collotype process, and where a pale color is to be reproduced, the loss of homogeneity spoils the effect. A homogeneous wash of pale blue, for instance, may artistically represent the sky, but where this wash is translated into a multitude of dark blue spots, giving a general impression of paleness on account of the white spaces between them, the effect is apt to be harsh and crude rather than artistic.

Besides this, there is the difficulty of getting each layer of ink of exactly the right density. If the yellow is printed a little too deep, for example, even though the crimson and blue may be just right, the mixed colors containing yellow will not be faithfully reproduced, and the general effect will be spoilt.

If these stumbling blocks and certain others not mentioned here can be overcome, no doubt trichromatic photography has a great future before it, since there is not even an indication at present of any method by means of which true color photography can be attained.

1. The Object of Functional Diagnosis and Some Remarks Concerning the Blood as an Organ, and the Regulatory Function of the Kidneys. O. ROSENBACH.
 2. The Technique and Value of Subcutaneous Injections of Quinine. BLUENCHEN.
 3. Further Facts Concerning My Method for Demonstrating the Presence of Human Blood. UHLENHARTH.
 4. Concerning Dr. M. Funck's Vaccine Germ. W. PODWYSSOZKI and A. MANOWSKI.
 5. Incomplete Oxidation of Sugar in the Human Organism. (Conclusion). P. MAYER.
- 1.—To be concluded.

2.—Bluenchen found that the muriate of quinine would dissolve readily in boiling water in the proportion of 1 gr. to 1 c.cm. and that it did not crystallize out of this water

when then cooled to body temperature. He therefore dissolves the muriate of quinine in boiling water in the strength mentioned, allows the solution to cool to a comfortable temperature and injects subcutaneously. It is important to pass the needle beneath and not merely into the skin. The solution may be thoroughly boiled to insure asepsis. The injections, when properly made cause no pain, indurations or other unpleasant results. The solution can be readily made, is cheap and acts well. [D. L. E.]

3.—Uhlenharth has found that injection of blood of one species into an animal of another species caused the production of some substance in the blood serum of the second animal which reacts with the first species of blood. A similar reaction is obtained by injecting a definite species of albumen into an animal of another species, but while the blood reaction seems to be practically wholly specific, reaction may be obtained with various closely related forms of albumen after injections of albumen. For instance, after injecting the albumen of hen's eggs, reaction may be obtained with the albumen of pigeon's eggs. He has previously shown that the reaction for human and other forms of blood is still specific even when the blood has been dried for months, and the most important part of this article is the report that blood that has been allowed to decompose for several months, or that had been kept for weeks, as well, as urine and menstrual fluid containing blood, gave the reaction perfectly and always a specific reaction only. The reaction was not interfered with by heating for an hour at 60° C., or by a number of preservatives, such as carbolic acid (0.5% solution). These facts are of great importance in relation to the medico-legal determination that blood is of human origin. [D. L. E.]

4.—The authors have found in vaccine pustules the objects described by Funck. (*Deutsch. Med. Woch.*, Feb. 28, 1901). They look upon them, however, from a wholly different point of view, considering them nothing but fatty epithelial cells and believing that they have no relation to the etiology of vaccine or variola. [D. L. E.]

5.—Mayer has found glycuronic acid in many affections that are often accompanied by slight glycosuria as well as in diabetes, and also in acute febrile diseases in which sugar is to be seen, not frequently found, but in which incomplete reactions for sugar are often observed. He has also found it in many instances of severe dyspnea and circulatory failure. In experiments on animals the latter conditions have repeatedly been found to be associated with glycosuria, but this is uncommon in human subjects. Mayer thinks that his results explain this difference between experimental and clinical results; the human organism like that of animals shows lessened oxidation under these circumstances, but in the former case the disturbance is less marked and shows itself only in a large output of glycuronic acid. He found in a dog that decreasing the oxygen intake caused a decided excretion of glucose but also a much more marked excretion of glycuronic acid. Further, after administering glycuronic acid to animals in large doses, he noticed signs of poisoning and found that their urine contained large amounts of oxalic acid, an evidence to his mind that glycuronic acid, like glucose may at times be incompletely oxidized in the organism, and that it is then excreted as oxalic acid. He also believes that this shows that during its oxidation sugar passes through the stage of oxalic acid. This was indicated too, by the fact that oxalic acid appeared in the urine in large amounts when animals were given very excessive quantities of sugar. This, Mayer thinks, settles positively the much discussed question as to whether oxalic acid is an oxidation product of sugar in the human organism. Mayer also found large amounts of glycuronic acid in 11 of 30 cases of diabetes, both when sugar was present, and when it was not, and he believes that this explains occurrence of incomplete reactions in diabetes when the actual glycosuria has disappeared and that examination for glycuronic acid may be of prognostic importance under such circumstances and may often be an indication that sugar is not wholly well borne when other methods of examination seem to show that it is. He also believes that the increase of unfermented carbohydrates in diabetes reported by Rosin and v. Valfthan (*Deutsch. Med. Woch.*, 1900, No. 31) was really an excessive glycuronic acid excretion. [D. L. E.]

VOL. VIII, NO. 4

JULY 27, 1901

\$3.00 PER ANNUM

The Surgical Treatment of Goitre.—The *Edinburgh Medical Journal* for July contains a very interesting and instructive article on this subject from the pen of Marmaduke Sheild, of St. George's Hospital, London. Mr. Sheild has had what may be considered a large experience for an English or American surgeon, having operated 42 times for this condition. His cases show very excellent results. But one died, hemorrhage being the cause of death. It is shown that many cases may be greatly benefited by the iodide treatment. When medical treatment fails the author believes in doing something surgical to relieve the patient. It is shown very clearly that the delayed operations are the ones giving the poorest results, and on this account it is urged that cases be submitted to operation as soon as it is found that medication is of no avail. When one considers the work and results of some of the continental surgeons, particularly Kocher, one notices particularly that Sheild has not followed the practice of these men. He has always used a general anesthetic, and he reports many cases in which he has simply opened the sac and applied carbolic acid. It is also his custom to enucleate the growth when possible. In all of these points he differs from Kocher, who at the 30th Session of the German Surgical Society reported his second thousand cases of extirpation of goitre, from Kraske, who at the same meeting reported 420 cases, and from Riedel, of Jena, who reported 500 cases. These surgeons, as a general rule, all employ local anesthesia and they all advocate extirpation when possible, instead of enucleation. Kocher has abandoned the thyroid extract treatment and Kraske condemns it quite heartily. They both recommend the iodide treatment. Kocher shows a wonderful mortality of 4% for all of his operations. Kraske asserts that greater hemorrhage will follow enucleation than extirpation. Regarding the anesthetics one can hardly but agree with those advocating local anesthesia. The immediate dangers of a general anesthetic are thus avoided, and the subsequent vomiting, which is so productive of hemorrhage. During the operation any interference with the recurrent laryngeal nerves can readily be avoided. Sheild's recommendation and habit, in very

large and adherent cystic goitres, of drainage, seems to us good. It is free from danger, and he has shown that although such cysts may drain for a long time, yet they ultimately close. Probably in no branch of surgery has so great advance been made as in the operative treatment of diseases of the thyroid gland, and much of the credit must be given to Kocher, of Bern.

Operations for Gall Stones.—The question of mortality after surgical operations is one that has always been of the greatest interest to the profession and to the laity. For in proposing any operation the first question asked by the victim is always: "What chance have I of dying or recovering?" In certain respects it is a needless question, because experience shows that although it appears to be the case that of a certain number of patients submitted to some particular operation, about the same number will always die in every hundred, nevertheless, a careful analysis usually shows also that a more thorough knowledge of the fatal cases would have shown that the outcome was not entirely unexpected. Perhaps no man in the whole world is more intimately associated with certain limited but definite lines of surgery than Kehr. In the past 10 years he has done more to determine the indications, and to improve the technique of operations upon the biliary system than any other man—we might almost say, than any other half dozen men. Therefore, when he discusses the mortality of operations for gall stones his opinion must be treated with the profoundest respect. Quoting his own statistics, (*Muenchener Medicinische Woch.*, June 4th,) he divides the cases into the following groups, for each of which he gives the percentage of mortality. First, 210 conservative operations, that is to say, cysticotomy and cystostomy, with 4 deaths: a mortality of 1.9%. Second, 113 cystectomies with 4 deaths: a mortality of 3%. Third, 106 choledochotomies, or drainage of the hepatic duct, with 8 deaths: a mortality of 7.5%; and fourth, 156 complicated operations, involving operations upon the stomach, intestine, and the pancreas, or in cases in which there was carcinoma, sepsis, or peritonitis, with 69 deaths: a mortality of 44%. Kehr has

grouped these cases chronologically, and it is remarkable how, in almost all the forms, the mortality has been greatly reduced. Thus, in the last 100 cases, there have been no deaths either in the group of cystostomies or in that of cystectomies, so that the mortality from a simple operation for the removal of a gall stone can be looked upon as practically null. Certain interesting features may be discovered from the statistics. First, that the mortality is much greater among men than among women; the proportion in the last 100 cases being 40% and 8%. This, Kehr attributes in part to the weaker resisting powers of the men, as the result of persistent abuse of nicotine and alcohol, although it is possible that the greater frequency of carcinoma of the pancreas in the male sex contributes to the result. Certain cases may be regarded as invariably fatal: those of diffuse purulent cholangitis, and those of carcinoma of the head of the pancreas. He gives a brief summary of the 16 cases that died in his last group of 100, and calls attention to the fact that 12 of them could not have been cured by any operation or by internal medication. When, however, it is impossible to determine before operation just what the condition is, it is advisable to operate in all very desperate cases, that is, to give the patient the benefit of even a remote chance, when the outlook is otherwise hopeless. It is interesting to note that Kehr, of all men, advises conservative treatment in the majority of cases, and is in the habit of sending at least one-half of his patients to Carlsbad. He admits that the disease is not cured, but merely rendered latent by these methods, but is rather inclined to be satisfied with latency if an operation can thus be avoided. Some of our enthusiasts for operations might possibly take a hint from this.

The Pathogenesis of Cancer.—Dr. John Marnoch has contributed a valuable article (*Lancet*, July 6th, 1901) to medical literature, in which he gives the results of a number of important experiments on the effects produced by transplanting healthy epidermis into deeper tissues, and he also discusses the work of other investigators in this field. It has never been satisfactorily explained why epithelium tends to spread over the surface of the body, or why epithelium tends to cover an indolent ulcer.

Kaufmann, in 1884, claimed to have successfully implanted skin into deeper tissues with the result that the submerged epidermis did not die, and that a cyst developed. D'Arcy Power, acting upon the supposition that chronic irritation is a factor in the etiology of cancer, induced chronic irritation of the mucous membrane of the vagina of guinea pigs, rabbits, and rats. He was able to produce new

growths resembling in some respects cancerous tumors. Beatson inoculated animals with cancerous tissue from the human subject, and also transplanted the ovary and testicle of the rabbit into animals, without positive results. In every instance the transplanted tissue was completely absorbed. Ljunggren succeeded in preserving sterilized patches of skin in ascitic fluid for a period of three months. This observer also transplanted pieces of skin preserved in this manner, upon a granulating surface with the result that they became firmly adherent and incorporated with the granulating tissue.

Dr. Marnoch tried a number of methods for transplanting epidermis into deeper tissue. In one of these experiments a small island of epidermis, not deprived of its blood supply, was covered with a flap of tissue from each side. In another experiment a piece of epidermis was excised and buried in muscular tissue. In still another experiment a piece of skin was anchored to the peritoneum. In every instance the results were practically the same, for invariably the epidermis died within a few days. This author emphasizes the fact that we are almost forced to conclude that the main reason which determines whether the transplanted healthy epidermis will live, is the fact that it has been placed upon an exposed surface.

The experiments of Marnoch show definitely that the mere transplantation of healthy skin into deeper tissues is not sufficient to cause multiplication of cells and a tumor, even under the most favorable circumstances. At the present time the important researches of Sanfelice, Gaylord, and others, although not conclusive, lend strong support to the view that the irritant which determines the multiplication of tumor-cells is of a parasitic nature.

Tropical Dysentery.—That increase in territory is not an unmixed blessing is very evident from the second circular on tropical diseases issued from the Headquarters of the Division of the Philippines. It is a careful study of tropical dysentery, by Lieutenant Richard T. Strong, U. S. A.

Lieutenant Strong recognizes two essentially different forms: acute specific dysentery, and amoebic dysentery. The latter appears, fortunately, to be the more common. The former may appear also in a sub-acute, and in a chronic form. The extreme seriousness of dysentery is shown by the fact that of 1830 men admitted to one hospital in a period of 16 months suffering from it, only 621 have been able to return to duty. Acute specific dysentery, that is, a form produced by the bacillus of Shiga, is easily recognized by the fact that it gives a specific agglutinative reaction with this bacillus. Strong has studied it very carefully, and his results agree essentially with those of other bacteriologists. He

gives a clinical description of the disease, which may be repeated briefly as follows: The incubation is probably not more than 48 hours. The onset is sudden and severe. There is high fever, occasionally moderate leukocytosis, and rapid pulse. Very rarely there is broncho-pneumonia, or bronchitis, or pleurisy. The patients complain of headache; the urine occasionally contains a small amount of albumin, but nephritis is a rare complication. Secondary changes in the liver are also uncommon. Recovery is exceedingly rare in the most severe cases, and unfortunately one attack does not protect against others. Malaria is a very rare complication. Post-mortem, the most characteristic changes are found in the large intestine, the mucous membrane of which is swollen and covered with a superficial necrotic layer of blood corpuscles, epithelial cells, granular cells, and bacteria. If this is removed the intestinal wall is seen to be intensely congested. The spleen and liver are not enlarged, and the other organs show changes so infrequently that they cannot be regarded as significant. Microscopically, extensive coagulation necrosis of the mucous membrane of the intestine is usually found. The serum reaction appears to be quite constant. In 246 cases of diarrhea and dysentery the blood was examined, and it was positive in 71. In 21 of these it was possible to examine the stools, and in all, the bacillus dysenteriae was obtained. In 3 cases the reaction was positive and amoebae were found, and in 5 cases the reaction was positive although amoebae or other animal parasites were not found in the stools. It is very likely that all these cases were instances of double infection. With regard to amœbic dysentery the most interesting point is the statement that 2 forms of this organism are found in the Philippines: amœba dysenteriae and amœba coli. The former is somewhat rarer than the latter; it frequently contains red blood corpuscles, and is associated with chronic manifestations of the disease, and is pathogenic. The latter may occur in the feces of patients perfectly healthy, and has no effect whatever upon cats. There are certain features in this report that are worthy of very careful consideration. In the first place, the extremely serious nature and the great frequency of dysentery in the Philippines; second, our present inability to cope with the disease, and third, the fact that one attack appears to afford no protection whatever. It is therefore urgently necessary that very thorough and careful studies should be made, in order to discover, if possible, some method of preventing infection, and possibly some serum that will effect a cure.

Hospital Appropriations.—There is reason to fear that some of the legislation in this State appropri-

ating money to hospitals is a very great abuse. Our sympathies are naturally with all laudable hospital enterprises, but we cannot shut our eyes to the fact that of all forms of "hospital abuse" the one which seeks public money for the furthering of private schemes is probably the most pernicious. The subject has too many phases to admit of full discussion here and now, but there is one aspect of it that can be referred to briefly, and will be easily understood by all. This is the fact that the legitimate and necessary hospital work of the State is in danger of suffering because of the indiscriminate demand from all sorts of small local institutions for public aid. We suppose it will be generally acknowledged that the care of the indigent insane is one of the first duties of the State. In fact there are few other classes of invalids (unless it be the epileptics) that should be charges upon the bounty of the State. Public polity, as a rule, does not regard it as a duty of the State to care for the sick, but a noble and necessary exception is made in favor of the insane. We hold that nothing should be permitted to interfere with this bounden duty, and that the various State Asylums should not be made to suffer in the general demand for largesse from other hospitals all over Pennsylvania. We feel impelled to make this statement because of the recent altogether reasonable complaints from the Norristown Asylum that it was to be made to suffer because of the economy forced upon the Governor by the great number of appropriations to hospitals which are not truly public or state institutions. There is no more important hospital in Pennsylvania than the Norristown Asylum. With an authorized capacity of 1710 patients, it is accommodating 2138 insane men and women. This should not be so. One of the first duties of the State is to its own, and we trust sincerely that this and other hospitals for the insane will not be allowed to go begging.

Smallpox in Pennsylvania.—Dr. Benjamin Lee, Secretary of the Pennsylvania State Board of Health, sends us the following statement about the prevalence of smallpox in this state. The 2000 cases referred to recently in some of the daily newspapers were the total number of cases that have appeared since the beginning of the epidemic in December, 1898—about two and a half years ago. This epidemic ended in November, 1900. The total number of cases for that period was about 1200 with 11 deaths. A second epidemic began in February of the present year, and continues up to the present time. There have been thus far 800 cases with 5 deaths. It is thus seen that the condition is not so alarming as might be inferred from some of the published statements. The mortality, moreover, has been astonishingly low, just as has been the

case all over the United States, except possibly in Louisiana. This mortality in Pennsylvania is less than 1%. This gratifying fact should be emphasized in all the newspapers which comment on these figures. The mild type of the prevalent smallpox in this country has caused much discussion. In what, if any, way it can be associated with increase of vaccination, does not very plainly appear. It is a blessing which we must accept in an unquestioning mood, unless the anti-vaccinationists can make it appear as an argument in their favor. But even this would be hard to do—except by an anti-vaccinationist.

The Statistics of Medical Education in the United States.—Despite prolongation of the term of study, of preliminary entrance examinations, and of other requisites for eligibility, as well as of State examinations for the license to practise their chosen profession, not to speak of the increasing difficulty in securing a remunerative clientele, the number of medical students continues to increase. Thus, according to the Report of the Commissioner of Education for the year 1898-99, it appears that there were enrolled in 150 schools during this period 23,778 medical students, an increase of 345 over the previous year. These schools owned ground and buildings valued at \$13,121,529, and had endowments valued at \$1,422,373, while their libraries contained 130,922 volumes. One hundred and twenty-two of the schools were regular, 21 homeopathic, 6 eclectic, and 2 physiomedical. There were engaged in teaching in the regular schools 3562 instructors, in homeopathic schools 636, in eclectic schools 131, and in physiomedical schools 60. Of the whole number of students there were enrolled in regular schools 20,338 men and 1,063 women, in homeopathic schools 1,487 men and 315 women, in eclectic schools 452 men and 48 women, and in physiomedical schools 65 men and 10 women. There were, in 1899, 4,314 graduates from regular schools, 433 from homeopathic schools, 152 from eclectic schools, and 12 from physiomedical schools. Of the graduates, 1,879 from regular schools, 103 from homeopathic schools, 57 from eclectic schools, and 14 from physiomedical schools possessed the degree of A. B. or B. S. All but 15 of the medical schools giving full courses of instruction, reported having a course of four years, and some of the remainder were preparing to enter upon such a course. In 43 schools the annual session continued eight months or longer, and in 12 of these the session continued for 9 months. It is pointed out that in several medical schools the time of attendance now required in one year is equal to the whole time of attendance required for a degree 20 years ago.

The Unreliability of Public Statistics.—We have on previous occasions called attention to the comparative valuelessness of the vital statistics as published by some Boards of Health on account of the want of uniformity, and lack of precision in nomenclature. Of this a cogent instance will be found in the figures published by the Philadelphia Bureau of Health for the week ended June 20th, and there is no reason to believe that the statement for this period differs in character materially from that of other periods. Taking the report seriatim, we find, for instance, that 18 deaths are ascribed to apoplexy. Now apoplexy is merely a symptomatic designation, and it may result from several causes, the principal of which are cerebral hemorrhage, embolism, and thrombosis, but there are other causes, such as uræmia, that may be attended with sudden loss of consciousness, with muscular relaxation or convulsions. Further, paralysis is made responsible for 8 additional deaths, softening of the brain for 4, and disease of the brain for 1. One death is attributed to atheroma, a disease of the blood vessels that may result in rupture or thrombosis and local necrosis, but per se it is scarcely a cause of death. One death is, in fact, charged to gangrene, and three more to arterial sclerosis. Four deaths are attributed to Bright's disease, 21 to convulsions, 3 to dropsy, 27 to inflammation of the kidneys, 1 to edema of the lungs, 12 to uræmia. Bright's disease must be considered synonymous with nephritis, of which both dropsy and uræmia, possibly with convulsions, are common manifestations, and to which, or to disease of the heart, edema of the lungs may be due. One death is charged to cholera and 20 to cholera infantum. Probably cholera nostras is meant by the former, as we have no knowledge of the existence at present of Asiatic cholera in this part of the world. "Disease of the heart" is responsible for 26 deaths, fatty degeneration of the heart for 3 besides, and inflammation of the heart for an additional 1. "Inanition" is charged with 17 deaths and "marasmus" with 10. We appreciate the difficulties of establishing a nosology that will at once meet all of the requirements, but we think we have clearly shown the need for a revision of the method of classification at present followed by the Philadelphia Bureau of Health.

Medical Advertisements in the Newspapers.—The times must be changing indeed. A Philadelphia newspaper, which has recently changed owners, advertises in the street cars in this city that it will print no advertisements of secret medicines. This is a sign of the times. Let us watch and see how carefully this straight and narrow path will be followed. When a newspaper is shrewd enough

to see that it is making a good bid for popular favor by turning down all quack advertisements, the medical profession can begin to feel that it has not bided its time in vain. There must, also, be some symptoms of popular regeneration (which have escaped us, but which our keener contemporary has detected) to induce it to enter upon such a delicate enterprise. The movement is auspicious. Heretofore the newspapers have been the great purveyors to the patent medicine consumers, but with this shining example before them they will no longer be able to plead business policy. The same journal announces that it will display no red ink. For this, too, we are grateful. There have been some distressing indications that red ink would yet disfigure medical journalism. This will help to save us from the polychromatic craze. Tempora mutantur!

Reviews.

Experimental Researches on the Central Localization of the Sympathetic, with a Critical Review of its Anatomy and Physiology, by B. Onuf, M. D. and Joseph Collins, M. D. Issued from the State Hospital Press at Utica, N. Y., June, 1901. Published Quarterly. Price, \$3.00 a Volume.

This fine monograph is issued under the auspices of the New York Pathological Institute, and is another of its publications that fully justify the high reputation of that much discussed institution. We cannot allow this opportunity to pass without calling the attention of the scientific world once more to the high character of the work that has been done in this Pathological Institute under the direction of Dr. Ira Van Gieson. Now that he has retired from the position of director it is all the more appropriate that we should speak in the highest terms of appreciation of the work which he did himself and which he fostered and encouraged in that laboratory.

The authors of this particular monograph are already well known in neurological circles, and their reputation will be distinctly enhanced by this present treatise. It is a thoroughly scientific work in a rather obscure domain of neuro-pathology, and is consequently not an easy one to review in a brief space. It is a work, moreover, which is very much needed and which should be in the hands of all working neuro-pathologists and clinicians. We think we are not saying too much when we characterize it as a thorough exposition of the subject of which it treats, while at the same time it is an adequate, although not completely exhaustive bibliographical guide. The prime object of the authors has been not so much to describe the minute histology of the sympathetic nervous system (a task, however, which they have performed very well), as it is to determine the manner in which the sympathetic is connected with or localized in the spinal cord and brain. It will be seen at once that this is the most obscure phase of this whole subject; the one about which light is most needed. The sympathetic nervous system has been too much kept out of count by neurologists. It is looked upon too much as a side issue; it is a dark corner into which they need not pry too closely or with which they are not especially concerned. Its connection with the central nervous system is too often ignored: its rôle in the causation of disease as well as in the production of symptoms has also been too glaringly slighted. It is to fill this gap in our knowledge that Dr. Onuf and Dr. Collins have composed this useful treatise. The essential part, then, we consider, is that which is devoted to the physiology of the sympathetic especially in its relation to the central nervous system. Upon this subject the authors have done a great deal

of praiseworthy original and experimental work, and it is sufficient here to call attention to that fact and to recommend the book as a trustworthy exposition of this department of neurology. The work, in fact, may be described as essentially an elaborate treatise on the physiology of the sympathetic nervous system, based upon a careful study of its anatomy and histology, and applied to the domain of pathology and clinical medicine. Among the subjects elucidated are the physiology of the lachrymal secretion, the secretion of sweat, the influence of the sympathetic on the pupil, and upon the various viscera, together with a study of the changes in the central nervous system caused by lesions in the sympathetic. The pathology of the sympathetic constitutes the fourth and last part of the book. It is a difficult subject to illumine, and we cannot say that the authors have drawn as extensively from neurological literature for the purpose of obtaining clinical illustrations as they might have done. We know from experience, however, that well reported cases are not numerous or easy to find. Drs. Onuf and Collins have discussed the relation of organic diseases of the brain and spinal cord, as well as the relation of functional diseases to this great auxiliary nervous system. Tabes dorsalis and syringomyelia are especially the two central diseases which are discussed in this relation. We should like to call the attention of the authors to the fact that some interesting cases of central nervous diseases, especially associated with hemiplegia, have been observed, in which affections of the sympathetic have occurred. Thus, one case in this city, recently reported, was in a man with hemiplegia who had hyperidrosis sharply limited to one side of the face and neck, with slight protrusion of the eyeball and dilatation of the pupil, a complexus of symptoms which evidently indicated an irritation of the sympathetic fibers within the central nervous system.

The illustrations in this work are particularly fine, and quite numerous. In conclusion we congratulate the authors upon the completion of a book which must have entailed very arduous labors, and we recommend the treatise to specialists in anatomy, physiology and neuro-pathology in the conviction that they will find it a valuable guide.

[J. H. L.]

Crazes, Credulities, and Christian Science, by Charles M. Oughton, M. D., Chicago. E. H. Colegrove. 1901.

Our first thought on reading this very excellent little book was one of regret that there could be any necessity in this country for the composition of such a work; our second thought was that the book would probably do little good where it is most needed. These reflections, however, were not inspired by any defects in the book itself, for it is an admirable and trenchant essay in criticism, but by the inherent hopelessness of the subject. We write deliberately when we write that there is an inherent hopelessness in this whole subject. The history of mankind proves conclusively that such crazes and crimes of credulity and superstition as Dr. Oughton seeks to expose, are the natural outgrowth of a rich but rank civilization. They are like the ill weeds that flourish in a rich soil which is not thoroughly tilled. The history of the Roman Empire during the earlier centuries of the Christian Era, is so illustrative of this fact, and so suggestive of some phases of our present condition, that we often wonder that the lesson from that source is not more fully recognized and more widely taught. Buckle pointed out most accurately that a people's literature does not advance before, but follows after their mental development. The stream will not rise above its source. Hence, in this country, our boasted popular education and our popular literature, being not above the level of the popular intelligence, furnish no adequate equipment for criticising and combating such rank impositions as Christian Science. A large number of people, in spite of a common school education and a reading acquaintance with the newspapers, will follow such a leader as Mrs. Eddy, and when her time is up they will follow some one else. The bellwether can always be found for a flock of human sheep. Such is the teaching of history. The only hope of civilization is in a higher, and still higher, education among the few who are capable of receiving it, and then a controlling influence exerted by the educated minority in state, in

church, in science and in society. The whole tribe of Eddyolators is not capable of being convinced; it must simply be controlled. [I. H. L.]

Eleventh Report of the State Board of Health of the State of Maine for the Two Years Ending December 31st, 1899. 8vo., pp. XII, 219. Augusta: Kennebec Journal Print, 1900.

In addition to the usual official matters, this report contains interesting papers on "Experiments With Disinfectants," by Dr. F. N. Whittier, of Bowdoin College; "Vaccination and Vaccine Lymph," by Dr. C. D. Smith, president of the Board; "Tuberculosis," by Dr. A. G. Young, secretary of the Board, and "Formaldehyd as a Milk Preservative," also by the secretary. Half of the volume is taken up by the essay on Tuberculosis, which is an especially praiseworthy and comprehensive article, and deals consecutively with the questions of infectivity, heredity, prevention, hygienic treatment and sanatoria. It seems a pity that the publication of this report should have been so long delayed. [A. A. E.]

Correspondence.

EYE AND EAR EXAMINATIONS OF RAILROAD EMPLOYEES.

By FRANK ALLPORT, M. D., of Chicago.

To the Editor of the Philadelphia Medical Journal.
Dear Sir:—

In your issue of July 6th, 1901, you print an article from my friend, Dr. Wm. Thomson, on "The Eye and Ear Examinations of Railroad Employees," which he calls "An Echo from the St. Paul Meeting of the American Medical Association."

My esteem for Dr. Thomson is so high that I hesitate to reply to his communication almost preferring to let it go unnoticed, but some impressions conveyed in his article are so unconsciously misleading, that I feel they should be corrected. In order that the matter may be fully understood, I beg leave to go back three years, when a Committee was appointed by the Ophthalmological Section of the American Medical Association to investigate the visual and aural qualifications of railway employees. I had the honor to be Chairman of this Committee. For various reasons unnecessary to explain, this Committee did not make a complete report to the Ophthalmological Section until the present year at St. Paul. In the meantime Dr. Thomson, of Philadelphia, had been selected to take the place of Dr. C. H. Williams, of Boston, who had resigned. In order to arrive at conclusions based upon facts, I communicated with every railroad in the United States, Canada and Mexico, operating over four hundred miles of road. Two hundred and forty-four railroads were thus addressed, covering two hundred and five thousand, six hundred and thirty-eight miles of road. I have received replies concerning methods of operation, etc., from almost every large railroad artery thus addressed, or in other words have heard from one hundred and twelve roads covering one hundred and forty-seven thousand, eight hundred and thirty-eight miles of road. The results of these inquiries, including statistics, etc., may be found in the Journal of the American Medical Association, October 13th, 1900, and in some subsequent issue of the Journal during the coming year, when the Journal takes up the work of the Ophthalmological Section in St. Paul. The major portion of this report with deductions was read at the meeting of the Association held in Atlantic City, in 1900. I may say without egotism that the paper was received with considerable favor by the Section, so much so that Dr. Thomson, himself, stated that he had been so much pleased with the paper, that he would like to make a motion to extend a vote of thanks to the writer, which motion was unanimously adopted. In the discussion which followed the paper, and which may be found upon page 126, of the issue of October 13th, 1900, of the Journal of the American Medical Association, Dr. Thomson distinctly states that the excellent method proposed by himself to

the Philadelphia Railroad System, was proposed by him as a "pioneer move, intending to take the place of nothing, and I hope it has been somewhat effective in protecting the public and the employees from the disasters of accident until the present time, when this advancement, that Dr. Allport has taken such a good part in bringing about, may be followed by something better. I agree with Dr. Allport that the examinations should be in the hands of oculists, wherever possible, and I shall be glad to call the attention of our railroad officials to these points."

It would, therefore, seem that Dr. Thomson was well pleased with the idea at the time of the Atlantic City meeting, and I cannot understand why he, at the present time, discourages a decided step in advance.

Several weeks before the St. Paul meeting I communicated with the different members of the Committee by letter, as it would have been impossible to get them all together, for they live in various portions of the country. I outlined a set of resolutions conveying the ideas we wished to express. With the exception of Dr. Thomson, the members of the Committee promptly replied to my communication. By dint of much corresponding, changing and remodelling, we finally formed a set of resolutions agreeable to all members of the Committee, except Dr. Thomson, who tardily (unless my memory fails me) wrote one short letter, after repeated solicitations, just before the St. Paul meeting and after the report, by much labor and many concessions had been unanimously approved by the other members of the Committee.

It seems that Dr. Thomson feels a duty pressing upon him to voice his views concerning the report of the Committee, which was presented before the Ophthalmological Section in St. Paul, and with the exception of one dissenting vote, unanimously adopted by the Section. It is to be regretted that Dr. Thomson did not consider it better wisdom to act with the other members of the Committee. Had he desired to freely express his views, as did the other gentlemen, and as he was repeatedly requested to do, it would doubtless have been possible to have harmonized matters, so that the report of the Committee might have been of a unanimous character. Dr. Thomson, however, waited until it was too late to harmonize matters, and then (failing to attend the meeting) sent his minority report, as he chooses to call it, to the Secretary of the Section, instead of to the Chairman of the Committee, as he should, in such a manner that it failed to reach its destination until the Chairman of the Section returned to his home in Memphis. In the meantime, those of the Committee, who were present at the St. Paul meeting, unanimously adopted the report, which was subsequently as it has been said before, almost unanimously adopted by the Section. The Committee was then discharged, having fulfilled the purpose which gave it birth. I cannot see that Dr. Thomson should complain. If he had anything to say, he might have come to St. Paul and said it, or, if this was impossible, he had ample time and was repeatedly solicited to put his views in writing and present them to the proper person, where I can assure him they would have received the respectful attention demanded by Dr. Thomson's high professional and personal position. He did not see fit to do this, however, and now that the matter has been closed, the report adopted, the Committee discharged, and the meeting adjourned, requests that his report be published in the Journal of the American Medical Association. The editor of that publication, after giving the matter due consideration, felt that, inasmuch as Dr. Thomson's report had not been presented at the St. Paul meeting, and inasmuch as the incident had been closed, deemed it best and wisest under all circumstances, to refrain from its publication.

A certain paragraph in Dr. Thomson's paper is most misleading, because he has chosen to quote a few words in the report, without reporting the preceding matter. I beg to quote Dr. Thomson's paragraph: "Dr. Allport's report must now be read, and will be found in the Journal for June 22d, 1901, page 1795. He demands that the work of testing the sight and hearing of railroad employees 'must be superintended by this Section,' and must be made by Eye and Ear Surgeons, etc., and in his pamphlet expresses the opinion that it were better if 'such examinations were never made by non-professional men.'" I now beg to quote the words of the Committee bearing on Dr. Thomson's remarks.

"Your committee, therefore, begs leave to submit to the

Section the following resolutions, which it is hoped will later be adopted by the American Medical Association, and then correctly placed before the proper railroad authorities of North America. This work should be superintended by this Section." It will be seen that the words "this work should be superintended by this Section" refer simply to bringing the matter before the general assembly of the American Medical Association, and then seeing that the necessary literature, etc., is placed before the proper railroad authorities of North America. Such an idea as the Ophthalmological Section of the American Medical Association superintending the examination of the eyes and ears of the railroad employees in this country is too ridiculous and preposterous for even a passing thought. In the same paragraph Dr. Thomson says that the report states that "such examinations must be made by Eye and Ear Surgeons." Dr. Thomson has evidently misread section two of the report, which says as follows: "Such Primary examination should, whenever possible, be made by regularly appointed Eye and Ear Surgeons, and this point is emphatically urged, especially as the expense of a first examination must always be borne by the applicant, but if such a course is not deemed expedient, the Company's Surgeon, aided by his medical assistants, may conduct them, with the understanding that all doubtful cases shall be sent to a regularly appointed Eye and Ear Surgeon." The words, "such examinations must be made by Eye and Ear Surgeons," were stricken out of the report at the request of one or two members of the Committee. Dr. Thomson states that in my article on the subject, presented last year at Atlantic City, I advised that such examinations should never be made by non-professional men. This is perfectly correct. It is my own individual opinion that the eyes and ears of those men directly engaged in running trains, should be examined by physicians (preferably ophthalmologists and otologists) and not by railroad employees. This, however, is simply my individual opinion, which I claim the right to maintain and retain, but this idea was not incorporated in the report of the Committee. I gave up my views upon this point, in order to harmonize and unify the report. In another section of Dr. Thomson's article, in speaking of the difference of opinion upon this subject, he says that, "even Mr. Nettleship, famous as a surgeon and writer, had failed to detect a color blind man by wool tests." It would seem as if this were an argument in favor of the examination of railroad men by physicians, and especially ophthalmologists: for if even as eminent a man as Mr. Nettleship is liable to err, certainly a non-professional employee could not in any sense be considered sufficiently expert for such examinations. But my object in this communication is not to criticize Dr. Thomson's personal views. These he has a perfect right to hold. I simply desire to place before those gentlemen in the profession, who are interested in the subject, this matter in its true light, and then they in their turn may form an opinion as to the actions of all those who have taken part in the proceedings.

I regret to be compelled to say anything on the subject for publication, but inasmuch as Dr. Thomson has taken the initiative, and inasmuch as it appears to me that several people will be misjudged if Dr. Thomson's article is not answered, I feel it my duty as Chairman of the Committee and Chairman of the Ophthalmological Section for the coming year, to endeavor to place the matter in what seems to me its proper light. My respect and admiration for Dr. Thomson are of such a high character, that this controversy is exceedingly distasteful to me, and I trust that the matter may be now terminated.

INFORMATION WANTED.

By JAMES M ANDERS, M. D., of Philadelphia.
To the Editor of the Philadelphia Medical Journal.
I should be excessively obliged to the subscribers of our valuable journal for answers to the following queries:
(1) In what percentage of the cases of chronic valvular disease affecting the mitral and aortic segments has pulmonary tuberculosis developed as a secondary event?
(2) If notes have been kept, kindly give the total number of cases, both of valvular disease and pulmonary tuberculosis, as well as the percentage.
(3) If no records have been kept, kindly state opinion as to the frequency of the occurrence of pulmonary tuberculosis secondary to chronic valvular disease at the orifices mentioned above.

- (4) What is the effect of valvular disease, mitral and aortic, upon the course of chronic pulmonary tuberculosis?
- (5) Have lesions of the pulmonary artery valves seemed to predispose to pulmonary tuberculosis? (Statistics on this head are also desired).
- (6) If chronic valvulitis affecting the mitral and aortic cusps exercises a preventive effect, what is the explanation?
- (7) If disease of the pulmonary valves (I refer especially to stenosis) predisposes to phthisis, how is the effect accounted for?

THE ANTI-CANTEEN RESOLUTIONS.

By W. B. GRAY, M. D., of Altona, Illinois.

To the Editor of the Philadelphia Medical Journal.
A prominent officer of the American Medical Temperance Society (of which the veteran, N. S. Davis, is president) makes the statement that the infamous anti-canteen resolutions of the American Medical Association were passed by a very small number of the doctors visiting in St. Paul. The matter was brought up before the Association, and the sentiment of the meeting was that the effects of the law should not be judged for two or three years, when results will be more apparent. The resolutions were laid upon the table by an enormous majority. However, the matter was referred to a committee, who met and reported to the few who were expecting it, during the meeting of the various sections, and the delegates supposing the affair disposed of for the year were attending to scientific matters, and so the resolutions were "carried unanimously" by about 25 men. It was not considered necessary to put the negative of the question. The result defines the position of the American Medical Association and all that is represented thereby. The people take many things for granted when they are published in the newspapers. So do Congressmen, and even medical editors, and so we next read the editorial of June 15th upon the subject. Those who agree with that article will admit that possibly some "men of sense" might be on the other side of the fence. Many good people are mistaken upon this subject because they have not tried to study the other side. They read what the newspapers serve to them, and this is influenced by those who desire to manufacture public opinion against this law. The distortions of fact, and the fabrications which have been used for this purpose and exposed by the prohibition press, and proved to be false largely by the affidavits of their opponents, are enough to make any lover of truth indignant. I hope it will not be repeated that "this act deserves to fail," for it is an effort of good people to do good. Let us not disagree over methods to the extent of helping the enemy instead of our allies. If saloons outside any army post are an evil, and produce disorder and crime, surely saloons plus the canteen will not be much different, surely not better. The canteen inside is of the same nature as the resort on the outside with the additional inducements towards drink of profits for the mess and hospital. Uncle Sam should not furnish the means to debauch his own soldier boys. If they have evil inclinations and we have no help to offer them, at least let them go astray through their own efforts, and not with our assistance. Let the abode of the soldiers be free from a persistent temptation thrust under their noses, and let the nation provide more elevating diversions than beer drinking for those young men who left good homes from a desire to serve their country. May we not rather take a patriotic pride that a virtuous public opinion can speak forth in such a manner that Congress is compelled to attend its behests. On a recent pay day at Fort Sheridan, 1300 men received \$15 each, and only 12% of them cared to invest in liquor at all. There was no disorder, and the 8 saloons outside do less business than in canteen days. Twenty-two railroads in America enforce total abstinence among their employees. Will any one dare to say that it is not a good thing for both travelers and for the men and their families? Let us not pronounce hasty condemnation upon the legislation of the grandmothers. There are many questions upon which their judgment would be more correct than that of certain smart Alexes whose talk we have heard. It would be unjust to allow two or three dozen men to wield the political influence of all the doctors in America as represented in the American Medical Association.

American News and Notes.

PENNSYLVANIA AND PHILADELPHIA NEWS.

Free Hospital for Poor Consumptives.—Dr. Lawrence F. Mick, president of the Free Hospital for Poor Consumptives, announces that a camp for male patients will be opened within a few days in White Haven, where the erection of buildings will be begun in the fall.

Hospital Work in Philadelphia During June.—Following is the work of some of the hospitals of Philadelphia during the month of June: The Charity Hospital, 1731 Vine street—Total number of patients treated, 919, of which 133 were medical, 193 surgical, 314 women and children; 8 were diseases of the nose, 56 of the throat, 21 of the ear and 112 of the eye; prescriptions dispensed, 1035.

Germantown Dispensary and Hospital.—Patients remaining June 1, 26 males and 28 females; admitted during the month, 56 males and 31 females, remaining July, 35 males and 23 females; treated in the dispensary 1164; medicines dispensed, 904; ambulance calls answered, 44; patrol visits made, 14.

Methodist Episcopal.—Patients admitted, 63; patients treated in the dispensary, medical, 29; surgical, 324; gynecological, 9; eye, 67; ear, 12; nose and throat, 32; skin, 6; total, 479; total visits to the dispensary, 1157; recent accidents, 320; patrol cases, 10.

Polyclinic.—New cases treated in the dispensaries, 1587; return visits, 5433; total, 7020; treated in the receiving ward, 572; admitted to wards, 87; discharged, 99; operations performed under ether, 63.

Presbyterian.—Patients remaining May 31, 221; patients admitted during June, 210; total number treated, 431, discharged, 233; remaining, 198, as follows: Men's medical, 30; men's surgical, 26; women's surgical, 22; children's ward, 2; private rooms, 26; Cathcart Home for Incurables, 27; Richardson Home for Convalescents, 17; treated in dispensary, 2364.

St. Agnes.—Medical cases admitted, 90; surgical, 77; gynecological, 6; total, 173; remaining in wards from May, 112; discharged during June, 134; total in hospital, 151; ambulance calls, 20; patrol cases, 64. Out-patient department: New cases, 456; old cases, 1651; total cases, 2507.

St. Luke's Homeopathic.—New patients admitted, 35, including 5 medical, 25 surgical, 5 gynecological; old and new cases treated, 55; remaining at end of month, 24; prescriptions to in-patients, 30. Out-patient department: New cases, 167; number of visits of old and new cases to dispensary, 865; prescriptions furnished to out-patients, 516.

Hospital and Dispensary of the Alumnae of the Woman's Medical College of Pennsylvania.—New patients registered, 330; surgical cases treated, 311; medical, 167; gynecological, 205; nose and throat, 221; eye, 901; children, 120; dental clinic, 65; skin, 32; treated by resident out of hours, 107; visits made by externe, 162; total, 1411, number of prescriptions, 775.

Hahnemann.—In-patient department: New patients admitted, 96; old and new patients treated, 181; pay patients, 80; free, 101; aggregate days patients in hospital, 1991; average days each patient, 11; prescriptions to in-patients, 1055. Out-patient department: New patients treated in emergency wards, 851; new patients registered, 1547; visits of all out-patients, 1765; treated at home, 21; visits to out-patients at home, 120; prescriptions, 3016.

Death of George E. Knode, M. D.—Dr. George E. Knode, aged 36 years, of Marklesburg, Huntingdon County, Pa., died at his home July 18th of tetanus resulting from an injury sustained by being thrown from a frightened colt. He graduated from the University of Pennsylvania in 1893. After graduation, Dr. Knode began the practice of medicine at Marklesburg, succeeding Dr. J. H. Wintrobe. He was a member of the Huntingdon County Medical Society, and took quite an active part in its transactions. At a special meeting of the Huntingdon County Medical Society, held July 18th, resolutions of condolence were adopted.

Vital Statistics of Philadelphia for the week ending July 20, 1901:

Total mortality	443	Cases.	Deaths.
Inflammation of the appendix 5,			
bladder 1, brain 11, bronchi 2,			
heart 1, kidneys 15, lungs 19, pericardium 1, peritoneum 1, pleura 1,			
stomach and bowels 25, spine 1..			83
Marasmus 20, inanition 23, debility 2			45
Tuberculosis of the lungs			61
Apoplexy 9, paralysis 6			15
Heart-disease of 27, fatty degeneration of 2			29
Uremia 3, Bright's disease 8, diabetes 3			14
Carcinoma of the breast 2, stomach 7, uterus 3, jaw 1, liver 2			15
Convulsions 20, puerperal 1			21
Diphtheria	28		5
Brain-softening of 1, tumor of 1			2
Typhoid fever	78		10
Old age			10
Scarlet fever	36		3
Abscess of liver 2, alcoholism 4,			
asthma 1, anemia 1, casualties 8,			
child birth 1, cholera infantum 58,			
cholera morbus 1, cirrhosis of the liver 2,			
cyanosis 1, diarrhea 5, drowned 1,			
dysentery 4, jaundice 1, locomotor ataxia 3, obstruction of the bowels 4,			
edema of the lungs 1, rheumatism 1, sclerosis, arterial 1, shock, surgical 2,			
septicemia 2, smallpox 1, sore mouth 2,			
sarcoma 1, sarcoma, breast 2, suicide 2, sunstroke 10, syphilis 1,			
tetanus 1, whooping cough 6			130

NEW YORK.

Examinations for Bacteriologists in New York City.—An examination for the position of Assistant Bacteriologist, Class I, salary \$800, will be held by the Municipal Civil Service Commission on July 29, 1901, at 10 A. M., and an examination for the position of Assistant Bacteriologist, Class II, salary \$1200, will be held on July 31, at the same place and hour. Candidates for Class II must be able to carry on original investigations. Subjects of the examinations are: Technical knowledge, experience, mathematics, writing a report on an assumed state of facts. Applicants should address Lee Phillips, Secretary, Municipal Civil Service Commission, 346 Broadway, New York City. For particulars as to the examination, application should be made to F. G. Ireland, Chief Examiner.

Long Island College Hospital Appointments.—Dr. Ralph H. Pomeroy has been appointed lecturer on obstetrics, Dr. John O. Polak, lecturer on gynecology and obstetrics, Dr. William F. Campbell, professor of anatomy, to take the place of Dr. W. W. Browning, deceased, Dr. Warren S. Simmons, adjunct professor of Anatomy.

NEW ENGLAND.

Hartford Abolishing Mosquitoes.—The Hartford Board of Health is abolishing the mosquito from nearby marshes by means of crude petroleum.

WESTERN STATES.

New Cases of Plague in San Francisco.—The *Journal of the American Medical Association* states in its issue of July 20th that bubonic plague has again broken out in San Francisco, four cases having already been reported. The first case was that of a Chinaman who died July 6th. He arrived in San Francisco a few days before from one of the lower islands on the Sacramento River, and was ill when he reached the city. An autopsy was performed, and the diagnosis of bubonic plague was verified by bacteriological examination. Since then three more deaths have been reported. These were Japanese women who were living in a brothel on Stockton street in the Chinese section of the city. In two of these the diagnosis was confirmed by bacteriological examinations. The result of the third is

not yet known. Two of these cases were ill with the disease a week before the Chinaman landed in San Francisco, so they have no relation to that case. Another case, which is not yet confirmed, is reported among the Japanese women. These are the first cases reported for three months, the last case reported by the Marine Hospital Service being April 4th. The local and State Boards of Health are now working more in harmony, and in unison with the Marine Hospital Service. The cleaning of Chinatown was completed June 22nd, but inspection and post-mortem examinations of Chinese have been continued under the direction of the Marine Hospital Service.

Northwestern University Medical School.—Owing to the illness of Dr. Frank S. Johnson, a change in the faculty of the Northwestern University Medical School in Chicago has been effected. Dr. Johnson retires as dean, and is succeeded by Dr. N. S. Davis, Jr., former secretary. Dr. Davis' position is filled by the election to the secretaryship of Dr. Arthur R. Edwards.

Hospital for Los Angeles.—A new emergency hospital is to be erected in Los Angeles, California, which will accommodate about 350 patients.

Dr. Christian Fenger, of Chicago, has been made an honorary member of the Association of Military Surgeons of the United States.

Dr. Alston Ellis, of Hamilton, O., has been elected president of the Ohio University at Athens, O.

St. Peter's Hospital, Helena, Mont.—It is stated that the trustees of St. Peter's Hospital, of Helena, Mont., have decided to erect a new building at a cost of over \$50,000. Over half this amount is now available, and the new work can be carried forth without the burden of debt.

The California Medical Law.—The following is an extract from the statute regulating the practice of medicine in California: Licenses are to be issued by a board consisting of five members elected by the Medical Society of the State of California, two members by the California State Homeopathic Medical Society, and two members by the Eclectic Medical Society of the State of California. Every person before practicing medicine or surgery, or any of the departments of medicine or surgery, in this State, must have the certificate provided for. In order to procure such certificate he must produce satisfactory testimonials of good moral character, and a diploma issued by some legally chartered medical school, the requirements of which medical school shall have been at the time of granting such diploma, in no particular less than those prescribed by the Association of Medical Colleges for that year or he must produce satisfactory evidence of having possessed such diploma, or a license from some legally constituted institution which grants medical and surgical license only upon actual examination, of satisfactory evidence of having possessed such license; and he must accompany said diploma or license with an affidavit stating that he is the lawful possessor of the same, that he is the person therein (named), and that the diploma or license was procured in the regular course, either of instruction or examination, without fraud or misrepresentation of any kind.

Licenses may be revoked by the Board on trial and conviction of unprofessional conduct, which is defined to consist in:

First.—The procuring or aiding or abetting in procuring a criminal abortion. Second.—The obtaining of any fee on the assurance that a manifestly incurable disease can be permanently cured. Third.—The willfully betraying a professional secret. Fourth.—All advertising of medical business in which grossly improbable statements are made. Fifth.—All advertising of any medicines, or of any means, whereby the monthly periods of women can be regulated, or the menses re-established if suppressed. Sixth.—Conviction of any offense involving moral turpitude. Seventh.—Habitual intemperance. The following persons shall be deemed as practicing medicine or surgery within the meaning of this act: 1. Those who profess to be or hold themselves out as being engaged as doctors, physicians or surgeons in the treatment of disease, injury, or deformity of human beings. 2. Those who, for pecuniary or valuable consideration, shall prescribe medicine, magnetism, or electricity, in the treatment of disease, injury or deformity of human beings. 3. Those who, for pecuniary or valuable consideration, shall employ surgical

or medical means or appliances for the treatment of disease, injury or deformity of human beings, except dealers in surgical, dental and optical appliances.—*E. S.*

SOUTHERN STATES.

The Mullet Key Quarantine Station, Florida, will be purchased by the Federal Government and managed by the Marine Hospital Service.

The West End Maternity Hospital, at Baltimore, was incorporated July 18th by Drs. Bernard P. Muse, Joseph H. Branham, John B. Schwatka, John William Funck, Frederick Caruthers, G. Milton Linthicum, W. Wayland France, C. Erban Smith, William S. Smith and William H. Peace, who are trustees for the first year.

The Wilmington Board of Health has ordered the executive officers to make an inspection of houses, with the view of a general cleansing of the city.

Dr. William H. Gobrecht, an eminent anatomist, and the author of a number of works on surgery and obstetrics, was found dead in bed at his residence in Washington, D. C., July 20. Dr. Gobrecht was 72 years of age, and a native of Pennsylvania. For several years he was Demonstrator of Anatomy at the University of Pennsylvania, from which he was graduated. At the time of his death Dr. Gobrecht was a medical expert in the Pension Office.

CANADA.

Meeting of the Ontario Medical Association, held at Toronto, June 19 and 20, 1901, (Continued). First Day, Evening Session. **Open-Air Treatment of Disease.** By Dr. George H. Carveth, Toronto, who described his method of treating different forms of disease, first, in the house with wide-open windows; second, in beds on the veranda; third, in beds under tents on the lawn. At first he experienced some difficulty in getting his patients to consent to be treated in this manner, but after they had become habituated to life in the open air, they returned indoors reluctantly. Some of the cases that he has treated in this way are iritis, cases of fracture, cases of the radical cure of hernia, rheumatoid arthritis, tubercular disease of the spine, typhoid fever, and a case of hysterectomy. His address was illustrated by lantern slide projections on the canvas, which proved very interesting to the members of the Association.

Dr. P. H. Bryce spoke of the value of treating smallpox patients in tents. The tents should be double roofed, and double floored, and double walled, and each tent provided with a stove. The patients lived in these when the thermometer was 20 degrees below zero, being quite comfortable. Nobody died, although many were seriously sick.

Dr. Freil, Stouffville, recited the history of the case of a clergyman, the victim of tuberculosis, who lived in his tent all winter when the thermometer was 20 degrees below zero, and the wind blowing a perfect gale, and he was very comfortable. In a few months' time he ceased sweating, and gained very rapidly in weight, to such an extent that delivering a sermon would not throw him into a perspiration as it always did before he took up tent-life on his lawn.

Dr. J. H. Elliott, Gravenhurst, saw no reason why outdoor life should not be employed in the treatment of other diseases as well as tuberculosis. It is not specific, and the only reason it is used is to strengthen the organism to resist disease. It is practically returning to primitive life, and it is so comfortable and pleasant that you find it very difficult to get patients to return to the house.

Dr. John Hunter referred to the Orphans' Home, Toronto, where they keep about two hundred children. These are admitted at about four years of age and they are kept there until they are about fourteen. Their mortality in that institution is about three in one thousand. They are practically kept out of doors all the time, and comparisons between the children of the Orphans' Home and the children of the well-to-do people of the city are greatly in the formers' favor.

Dr. Webster—The trouble is not so much to get the patients to sleep out of doors as it is to get them to return to the house when they have once been out of doors.

Dr. G. S. Ryerson, speaking of his visit to South Africa, said that at Bloemfontein the typhoid fever patients did particularly well in tents. The mortality was much larger in buildings improvised and used as hospitals. He con-

sidered that it was well to have the roof of the tent of material of some dark color, such as green or brown, because the patient, lying on his back, begins to complain of the color of the roof.

On the Use of Nitrous Oxide and Ether as an Anesthetic.

This paper was prepared and read by Dr. L. Coyteux Prevost, of Ottawa, and it proved to be highly interesting, carefully prepared, and ably delivered. He considers that a good and satisfactory anesthetic must possess the following qualities: First, offer the least possible harm to the patient; second, be rapid; third complete; fourth, permanent; fifth, followed by as few disagreeable post-operative effects as possible. He then proceeded to relate the results of his personal experience during the last two years at the hospital in Ottawa, as well as in his private practice. Dr. Carroll of Ottawa, was his assistant in this work. The agent they employ is ether, with which they lately have associated nitrous oxide, which is given at the beginning of anesthesia by the means of Clover's Inhaler. He considers this method as absolutely ideal, as much for the rapidity with which the patient becomes anesthetized as for the freedom from all unpleasant sensations during the process of anesthetization and the diminution of after-symptoms so frequent after operations. The apparatus which they have been using for the nitrous oxide and ether is Hewitt's Inhaler, which is a modification of a Clover Inhaler, with a rubber bag replaced by a large bag with valvular attachments. Within the last two years they have used this method almost exclusively, and the results are as follows: Anesthesia in one minute, twenty-four times out of three hundred and seven cases recorded in one and a half minutes, fifty-five times; in two minutes, ninety-four times; in two and a half minutes, forty-seven times; in three minutes, forty-four times; in three and a half minutes, nine times; in four minutes, nineteen times; in five minutes, fourteen times. Dr. Prevost then entered into his observations with regard to the effect of the anesthetics upon the kidneys, and stated out of 434 observations albumen was found twenty-six times. He drew attention to the fact that post operative vomiting was very rare. Dr. Prevost was the first surgeon in Canada to employ intraspinal cocainization. He believes that so long as the old and well-tried anesthetic agents, handled by competent men, continue to give good satisfaction that it will not be wise to abandon them until medullary narcosis has been clearly demonstrated.

The Complications and Degenerations of Fibroid Tumors of the Uterus, with Reference to the Treatment of These Growths.

Dr. Chas. T. Noble, Philadelphia, delivered an able and exhaustive paper under the above heading, an abstract of which will be published in a subsequent issue.

Drs. J. F. W. Ross, N. A. Powell, McKinnon, and Clouse discussed the paper, to which Dr. Noble replied.

SECOND DAY—MORNING SESSION.

The Relations of Nasal Obstructions to Obscure Cases of Asthma.—This paper was read by title by Dr. Arthur W. Mayberry, of Toronto. Patients suffering from nasal obstruction are frequently coming before the notice of the busy practitioner. Asthma has a complex etiology, and the close association of this disease with nasal trouble is sometimes very remarkable. Adenoid growths in the thorax frequently cause asthma, and in recent years much stress has been laid on the nasal origin of this disease. The author quoted Hosworth, who goes so far as to assert that asthma, in a large proportion of cases, is attributed to some form of nasal obstruction, the bronchial spasm being caused through reflex sympathy conducted along the fifth nerve.

On the Importance of an Early Recognition of Locomotor

Ataxia—Do the Eye Symptoms Assist Us?

Dr. J. T. Duncan, of Toronto read a paper, and emphasized the importance of being able to diagnose this disease in order that prompt treatment might be applied. To do this we must be able to recognize the pre-ataxic stage. What are these symptoms? Professor Osler gives them as pains, ocular symptoms, and loss of the knee jerk. What are the ocular symptoms? Strabismus or squint; ptosis or drooping of the eye lid; the fixed pupil (the Argyll-Robertson pupil); inequality of the pupils and optic atrophy.

Notes on the Use of Adranalin.—Dr. D. J. Gibb-Wishart, Toronto. This is the formula which Dr. Wishart has been using in his office practice, having made several hundred

applications, chiefly to the mucous membrane of the nose; one in one thousand, the chloride being dissolved in normal salt solution containing 0.5 per cent. chlorotone solution. A 10 per cent. dilution of the above solution, which dilution is equivalent to one in 10,000, has been sufficient to contract the blood vessels in the membranes in a few seconds, and a repetition of the same, or the use of a stronger dilution, will blanch these membranes; especially is this seen to be marked in the nose, where the membranes will become tightly drawn over the turbinated bones, which show up white through them. It has proven itself to be highly useful in rendering operations about the nose practically bloodless; it is not found to answer well in the removal of adenoids or enlarged tonsils. Dr. Wishart mentioned two cases in particular where it acted very promptly. The bottle in which it is kept must be tightly corked; and the properties of the substance are not destroyed by heat. Since he has added chlorotone he is perfectly satisfied as to the stability of the preparation for all practical purposes. In no instance has there been a tendency to increase in the amount of bleeding. Dr. Wishart comments that the drug is a valuable addition to our armamentarium.

Dr. Duncan's paper was discussed by Dr. Wishart, Dr. Crow, and Dr. Hunter; while Dr. Wishart's paper brought out a discussion from Dr. Trow, Dr. McPhedran and Dr. Graham Chambers. Dr. Wishart and Dr. Duncan replied respectively.

(To be Continued).

Obituary.—Dr. S. F. S. Wason, at Black River Falls, Wis., July 15, aged 73 years—Dr. Samuel Caley, at Mount Holly, N. J., July 16, aged 60 years—Dr. Sanford T. Riddell, at West Superior, Wis., July 16—Dr. George A. Blanchard, at Scranton, Pa., July 19—Dr. Wm. Henry Gobrecht, at Washington, D. C., July 19, aged 72 years—Dr. T. W. Leftwich, at Bedford County, Md., July 18, aged 70 years—Dr. Adolf Dunbar, at New York City, July 21—Dr. H. E. Raub, at Quarryville, Pa., July 20, aged 71 years.

Changes in the Medical Corps of the Navy, Week Ended July 20, 1901.

ASSISTANT SURGEON F. M. BOGAN, detached from the Scorpion, when put out of commission, and ordered to the Michias—July 17.
P. A. SURGEON C. P. BAGG, detached from the Culgoa and ordered to the Yorktown—July 17.
SURGEON C. J. DECKER, detached from the Newark, when put out of commission, and ordered home to wait orders.—July 18.
ASSISTANT SURGEON W. H. BUCHER, detached from the Naval Hospital, Norfolk, Va., and ordered to the Dixie, July 22—July 18.
ASSISTANT SURGEON P. E. McDONNOLD, ordered to duty at the Naval Museum of Hygiene, Washington, D. C., July 25—July 18.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended July 19, 1901.

GREAT BRITAIN.

British Congress of Tuberculosis. The British Congress of Tuberculosis was opened on July 22 by the Duke of Cambridge, president of the congress. Lord Lansdowne, the Foreign Secretary, also welcomed the delegates, and in the name of the Government promised all the assistance the Government was able to afford the congress. Lord Lister conveyed the thanks of the Congress to Prof. Robert Koch, of Germany, and the other scientists present for their attendance. A telegram was read from King Edward to the Duke of Cambridge, expressing the hope that "the result of the deliberations of the congress will be to assist the world in mitigating this dire disease which has bailed the most distinguished physicians for so long." The Duke of Cambridge announced that a gift of £120,000 would be forthcoming for the purpose of establishing the first public tuberculosis sanitarium as soon as the recommendations of the congress concerning its establishment had been formulated. Four hundred foreign delegates attended the opening session; they included a number of Americans and Canadians, among whom was Joseph H. Choate, the American Ambassador.

Dr. Koch's Address at the British Congress of Tuberculosis.—The address of Prof. Robert Koch before the British Congress of Tuberculosis was a notable event. His address occupied almost an hour and a half, and was read in English. Among some of the conclusions deduced by Koch were that hereditary consumption was extremely rare, and that the chief source of infection was the sputum. Recent experiments in Berlin, according to Koch, have shown that human tuberculosis could not be transferred to animals. The opposite, that human beings were not susceptible to bovine tuberculosis as communicated through dairy products, is of especial interest in that this opinion is opposed by no less a savant than Lord Lister. The natural preventive measures, Koch believes, are the removal of tubercular individuals from overcrowded dwellings and erection of special hospitals for them. Compulsory notification is essential, as well as thorough and systematic disinfection of the sick room. In addition, sanatoria should be established. Koch believes that the ultimate eradication of tuberculosis is possible.

Typhoid Fever in South African Army.—In the British army in South Africa 19,000 cases of typhoid fever have occurred, and 5000 have proved fatal.

Machines for Cleaning Pavements.—The convenor of the Sanitary Committee of Dundee Town Council and the Inspector of Cleansing have at present under consideration the subject for cleaning public pavements.

London Board of Health.—The new Medical Officer of Health in the City of London has just issued his first report to the Corporation. It deals with the sanitary condition of the city during the six weeks ending June 22nd. The special point in it is the reference to tuberculosis which he strongly recommends shall be placed in the category of contagious diseases.

CONTINENTAL EUROPE.

Dr. Alexander Kolisko, Professor of Medical Jurisprudence at the University of Vienna, has been elected Dean of the Medical Faculty.

Dr. Ludwig Rydygier, Professor of Surgery at the University of Lemberg, has been elected Rector of the University.

Dr. Karl Klecki, extraordinary Professor, has been made ordinary Professor of Pathology at the University of Krakau.

Dr. Edouard van Beneden, of Liège, Belgium has been elected foreign correspondent of the French Academy of Sciences.

Dr. Max Neisser has been appointed Professor of Hygiene at the University of Breslau.

Dr. Sigalas has just been elected professor, to fill the recently created chair of pharmacophysics, at the University of Bordeaux.

Dr. Bureau has been made a member of the French Academy of Medicine. Six hundred and ninety-six theses passed the Paris Faculty of Medicine in the year 1900-1901.

Dr. Galtier, of Lyons, has been elected an associate member, while **Dr. Livon,** of Marseilles, and **Dr. Motais,** of Angers, were elected foreign correspondents.

Leprosy in France.—Leprosy, which was scarcely known in France twenty years ago, is now very prevalent in Brittany and Savoy, and according to a recent report by Dr. Besnier, of the *Académie de Médecine*, these localities are now recognized leprosy centers.

Plague at Oporto.—The *Madrid Correspondencia* of June 26th, states that 12 cases of plague and four deaths have occurred at Oporto.

The Bacillus Discovered by Danysz.—The assertions of Danysz in regard to the pathogenic power of his bacillus have been confirmed by the tests at the Hamburg Institute, reported in this communication. All rats fed with cultures of this bacillus died in five to seven days, and white mice still earlier. There is no danger of confounding this bacillus with that of the plague.

Gift from the Sultan of Turkey.—It is stated that the Sultan of Turkey intends to present to the Berlin Hospital a wing, the plans of which have been sent to Emperor William for approval.

International Leper Law.—According to the *Semaine Médicale*, Germany, Persia, Roumania, Russia and Turkey have conjointly adopted laws for the purpose of preventing lepers from going from one of these countries to another. Passports and naturalization papers are denied lepers by these governments.

A Hospital for Tuberculous Children in Italy.—Upon the occasion of the birth of the Princess Yolande, the King of Italy has given \$10,000 with which to found a Hospital for Tuberculous Children.

Spinal Cocainization for Sciatica.—It is stated that Manega and Pullé, in Italy, have claimed to have cured a case of intense pains in the lower members accompanying hemiplegia and one of rebellious sciatic neuralgia, by the subarachnoid injection of 15 mg. of cocain or .75 c.c. of a 2 per cent. solution of cocain. The pains were abolished with a single injection, and have not returned.

A New German Society.—A German society for the study of medicine and the natural sciences has recently been formed. The committee of organization consists of Prof. G. W. A. Kahlbaum, of Basel; Prof. J. Pagel, of Berlin; and Dr. Sudhoff, of Hochdahl. The society will hold its first annual meeting after the close of the meeting of the Association of German Scientists and Medical Practitioners.

The Latest Literature.

BRITISH MEDICAL JOURNAL.

July 6th, 1901.

1. An Address on our Duty to the Consumptive Bread-Earner. SIR J. BURDON-SANDERSON.
2. A Clinical Lecture on the Arrest of Pulmonary Tuberculosis. C. THEODORE WILLIAMS.
3. A Clinical Lecture Introductory to the Use of Inspection of the Lung and Pleura. SIR JAMES SAWYER.
4. On the Diagnosis of Pleural Effusion by the Röntgen Rays. HUGH WALSHAM.
5. Four Cases of Primary Thrombosis of Cerebral Veins and Sinuses in Children. THEODORE FISHER.
6. Syphilitic Meningo-Myelitis; Erysipelas; Recovery. E. F. TREVELYAN.
7. Cerebral Tumor at the Parieto-occipital Fissure. R. T. WILLIAMSON.

1.—Sir J. Burdon-Sanderson, in an address on "Our Duty to the Consumptive Bread-Earner," discusses the general conditions of the problem, and especially the beneficial influence of residence in sanatoria. Speaking of Great Britain, he believes that the essential conditions relating to establishing suitable sanatoria depend upon the choice of suitable sites and the maintenance of suitable buildings as well as the selection of suitable cases and their prompt admission. He believes that the length of residence of each individual should be regulated by suitable medical supervision, and that there should be medical supervision of invalids after they are discharged from the hospital.

[T. L. C.]

2.—C. Theodore Williams in a clinical lecture on "The Arrest of Pulmonary Tuberculosis," discusses the pathology of the arrest of tubercle. If a tubercle mass has been quiescent and gives rise to no signs or symptoms, we generally assume that it is encapsuled and that all connection with a bronchus is cut off. There is another form of arrest in which the tuberculous mass becomes obsolescent, and is surrounded by chronic local pulmonary emphysema, which often prevents the detection of the tubercle by physical signs. A not unfrequent and conspicuous form of arrest of consumption is that in which a cavity situated in the upper lobe of one lung, undergoes contraction, and we are able by physical signs to recognize the various steps of the process. The increase of fibrosis causes a shrinking of the whole lung, the walls of the cavity approximate, and in some cases meet and cicatrize. In addition to the fibrous transformation of tubercle, there is a calcareous degeneration. The study of this subject has convinced the writer that the permanent arrest of tuberculosis is not a simple matter, but is surrounded with considerable difficulties. On the other hand, there are certainly a large number of instances of arrest of consumption revealed to us in the post-mortem room. [T. L. C.]

4.—Hugh Walsham reports two cases in which the X-rays were employed satisfactorily in the diagnosis of pleural effusion. Illustrating that in doubtful cases of pleural effusion, the Röntgen rays will enable us to see whether fluid is present or not; and from the density of the shadow to give an opinion as to whether such fluid be serum or pus. [T. L. C.]

5. Theodore Fisher reports four cases of primary thrombosis of the cerebral veins and sinuses in children. In the first case the superior longitudinal sinus was found to contain a partially decolorized and softening clot throughout its length which obstructed about one-half of the diameter of the lumen. All the veins running up to the superior longitudinal sinus on the right side of the brain, were full of pale clots, as were a large number of veins over the left cerebral hemisphere. The onset of the cerebral symptoms in this case occurred nearly a month before death, which suggests that the cerebral veins were first affected. In the second case the meningeal veins over both hemispheres were thrombosed, the meninges intensely congested and the convolutions were studded with petechiae. Both lateral sinuses contained a little ante-mortem clot. In the third case the choroid plexuses and the veins of Galen were thrombosed. This thrombosis was secondary to summer diarrhea. In his fourth case the

middle cerebral vein was completely blocked by the thrombus. [T. L. C.]

6.—E. F. Trevelyan presents a case of syphilitic meningo-myelitis complicated with erysipelas. Recovery followed. The point of peculiar interest in the case being that the attack of erysipelas was followed by improvement in the paralytic symptoms. There is reason to believe (but unfortunately the notes could not be found) that the patient was under antisyphilitic treatment during at least a part of the 12 months preceding the paralysis. [T. L. C.]

7.—R. T. Williamson reports a case of cerebral tumor at the parieto-occipital fissure. The chief interest of the case was the locality of the tumor confirmed by autopsy, and the three unilateral convulsions from which the patient suffered which began in the left leg. The case shows that a tumor at the most anterior part of the occipital lobe and at the parieto-occipital fissure, may produce convulsions commencing in the leg through the extension of the growth into the most posterior part of the superior parietal and quadrate lobules for about half an inch. This would coincide with the view that the leg center extends backwards both on the convex and median surfaces of the cortex almost up to the parieto-occipital fissure. In the early period of the case, no hemianopsia could be detected, and optic neuritis soon led to blindness. The only mental symptoms were dulness and delay in answering questions. [T. L. C.]

LANCET.

July 6th, 1901.

9. A Case of Extensive Enterectomy. ARTHUR E. BARKER.
10. Preliminary Note on the Direction of Air Currents in Nasal Respiration. CHARLES A. PARKER.

2.—Treated editorially.

3.—C. H. Leaf and H. W. Syers report an interesting case of tuberculous ischio-rectal abscess, complicated by lardaceous disease of the kidneys. The abscess was operated upon in the usual way; and in spite of the kidney condition and the fact that a division of the sphincter was necessary, the wound nearly completely healed, and the patient very greatly improved in general condition. The case is cited as a peculiar one because of the existing kidney condition with a tuberculous lesion. [J. B. G.]

4.—Pope discusses the physical causes of the slight forms of mental defects in children. Granting the theory, that a large percentage of those cases can be accounted for by pathological causes acting upon congenital weakness of hereditary origin be correct, does it afford any reason for believing that such conditions are likely to increase or to decrease? The cases dependent upon heredity will probably continue about the same for a long time, as a State legislation of marriage appears as yet to be far distant, and such a law will almost be the only measure that will control them. The number of cases will, no doubt, be prevented from increasing, even if they do not diminish, for reason of the law of reversion to type and intermarriage with healthy stock. He contends that women who bear more than a moderate number of children are likely to bring weakly ones into the world. The same applies to women much over 30 years of age. [F. J. K.]

5.—A. L. Whitehead reports a case of glaucoma following an iritis in which the tension was +3 and the vision re-

duced to counting fingers at six inches. Paracentesis of the anterior chamber gave no relief and an iridectomy could not be satisfactorily performed on account of an extensive posterior synechia. Another paracentesis, an attempted iridectomy, and a sclerotomy, all failed to reduce the tension. The superior cervical ganglion of the sympathetic was excised and immediately after operation the tension of the eye ball fell rapidly to $+\frac{1}{2}$, although there was no contraction of the pupil on account of the adherence of the iris described above. The tension fluctuated from day to day, but improvement in vision progressed and was maintained, until the tension remained but $+1$ and the vision equaled an ability to count fingers at 8 inches. The literature on the subject is reviewed. [M. R. D.]

6.—Williamson gives a report of the **pathological changes found in a case of progressive muscular atrophy**. Miller's fluid was used for hardening the specimens, and collodion as the embedding material. The tissues were stained according to the methods of Weigert and Marchi, and also with aniline blue-black and hematoxylin. Heller's pyrogallol and osmic acid method was used to demonstrate the nerve roots. The crossed and lateral pyramidal tracts of the white matter in the lower and middle cervical regions on transverse section appeared quite normal. The white matter of the anterior and lateral columns of the cord, and the direct pyramidal tracts were normal, except for a slight excess of neuroglia connective tissue in the direct cerebellar tracts. There was also a very slight excess of neuroglia connective tissue in the posterior median columns. The anterior horns of the gray matter were rather small. In both anterior horns the ganglionic nerve cells were absent, and after studying a number of sections the author was able to find one atrophied nerve cell in the median region of one anterior horn. It was very evident that the nerve fibers in the anterior horns of the gray matter had disappeared, and there was also a decrease in the number of fine delicate nerve fibers in the anterior horns. In the posterior horns the nerve fibers presented a normal appearance. The nerve fibers entering the median side of the posterior horns were normal, whilst the fine fibers of the surrounding median gray matter were decreased in number. In the anterior horns the nuclei of the neuroglia seemed to be increased in number. The anterior nerve roots consisted chiefly of fibrous connective tissue and empty sheaths and a few normal nerve fibers, while the posterior roots were normal. The walls of the small blood vessels of the anterior median fissure and the anterior horns of the gray matter showed a marked hyaline thickening. The upper cervical region presented a similar appearance. The upper and lower dorsal region also appeared normal. A few of the nerve cells in the anterior horns and in Clark's columns were pigmented. There was a slight increase in the connective tissue of the musculo-spiral nerve, but the bundles of nerve fibers were normal. The muscular tissue from the back of the forearm was soft and flabby, and there was slight resemblance to normal muscle. These changes were confirmed by microscopic examination, for not a single striated muscle fiber could be found. The muscle sheaths were collapsed and contained numerous round or elongated nuclei. Loose connective tissue and a few clusters of large fat cells existed here and there between the collapsed bundles. The muscular fibers did not reveal hyaline or fatty degeneration. This case is of particular interest because the crossed or lateral pyramidal tracts presented no evidence of degeneration. The author concludes that both clinically and pathologically there is a small group of cases which differs from amyotrophic lateral sclerosis. The case the author has described is an example. He believes that the old name of progressive muscular atrophy should be retained for these cases. [F. J. K.]

7.—Thesilian reports six cases of tetany. The first occurred in a male infant, aged 7 months; the second in a male infant, aged 15 months; the third in a female infant, aged 3 months; the fourth in a female child, aged 2 years; the fifth in a woman, aged 41; and the sixth in a woman 53 years of age. [F. J. K.]

8.—T. E. Hayward and R. G. Henderson report a case of **multiple epithelioma of the tongue** of a woman 25 years of age, in which the ulcer on either side of the tongue finally united in the center, causing an amputation of the anterior portion of the organ. The portion cast off measured about one inch by an inch and a quarter. The patient finally

died from exhaustion. The case is interesting because it shows certainly two and possibly three points of separate epitheliomatous growth. The age of the patient, as well as the sex, is unusual. Butlin states that a number of cases of double epithelioma have been reported, but none in which there were more than two points of disease.

[J. H. G.]

9.—Arthur E. Baker reports the case of a woman 39 years of age on which he operated for **strangulated femoral hernia**. The intestine was found quite dark in color, but had not lost its lustre, and improved upon washing with warm water after a division of the constriction. Excepting that the patient had some flatulency after the operation, she made an uneventful recovery. Subsequent to the operation the patient had several attacks of intestinal obstruction, the interval between the attacks being a number of weeks. About three months after the operation, however, the patient barely escaped death in one of these attacks. It was then decided to open the abdomen. This was done, and the portion of the bowel which had been herniated was found to be much constricted and matted together. It was impossible to separate the adhesions, so 37 inches were resected. The patient recovered very satisfactorily after this second operation. The case illustrates the importance of early operation in all cases of strangulated hernia, and shows that although the intestine may be in an apparently good condition, yet it may give rise to trouble after it is returned to the abdominal cavity.

[J. H. G.]

10.—Parker conducted experiments in order to determine the **direction of air currents in nasal respiration**. By means of an insufflator held about 8 inches from the nose, he impregnated the air with lycopodium. After quiet and forcible inspiration he observed the deposition of the powder within the nasal cavities. He determined the course of the expiratory current for both gentle and forcible expiration by carefully observing tobacco smoke exhaled through the nostrils. He suggests that a spray of lycopodium be used for practical diagnostic purposes in order to determine any irregularities which are causing obstruction in the nasal cavities. He found that during quiet inspiration the current of air traversed the middle, the superior, and probably the fourth meatus, and never the inferior meatus in the normal nose. Enlargements of the inferior turbinates seem only to interfere with inspiration when they form an obstruction to the entrance of air into the middle meatus. Great interference with nasal respiration occurs from polypi and enlargements of the middle turbinates. Considerable hindrance to inspiration also occurs from hypertrophies and growths springing from the roof of the naso-pharynx. During expiration the air current traverses the inferior meatus chiefly. An obstruction to this cavity necessarily interferes greatly with expiration. [F. J. K.]

MEDICAL RECORD.

July 20th, 1901.

1. The Suture of Wounds of Large Blood Vessels, with Report of a Case of Recovery After Suture of a Wound of the Axillary Artery.

A. E. HALSTEAD.

2. Clinical Observations on Syphilis. J. A. FORDYCE.

3. Headaches. H. H. Seabrook.

4. The Tampon in Gynecological Therapy.

MAXWELL BENJAMIN.

5. Latent Pulmonary Tuberculosis. CHAS. R. UPSON.

6. Mediate Palpation. E. W. WHITNEY.

1.—A. E. Halstead reports an interesting case in which, during the removal of a recurrent carcinoma of the breast, he accidentally cut through about two-thirds of the circumference of the axillary artery. Since at the previous operation most of the collateral vessels had been ligated, it was feared that gangrene would result from ligation of the axillary vessel. Digital compression was made on the proximal side of the injury and the wound closed with catgut sutures, which passed through the two outer coats. The patient left the hospital at the end of two weeks perfectly well, and two months after the operation the radial pulse on the injured side was as good as the other. The history of the suture of wounds of the blood vessels is reviewed and the technique of the operation discussed. When more than $\frac{1}{2}$ of the circumference of the vessel is involved it is advised that an end-to-end anastomosis by

invagination should be employed. This is apt to result in subsequent obliteration of the vessel from endothelial proliferation. In the meantime, however, the collateral circulation has been established. Temporary ligation with silk and catgut to prevent bleeding during the operation of closing the wound should not be employed. In his experiments upon dogs the author has found great satisfaction in the employment of tape twisted around the vessel until the circulation is controlled and then clamped with forceps. In suturing longitudinal wounds of arteries it is recommended that a continuous catgut suture should be used, passing only through two outer coats of the vessel.

[J. H. G.]

2.—J. A. Fordyce, in presenting some clinical observations on syphilis refers to a case of gangrene of the initial lesion which spread rapidly, and in two days involved $\frac{1}{2}$ of the glands. In this condition the author has found chlorinated soda solution either in full strength or diluted to suit the tolerance of the patient of great advantage. The author discusses at some length the various means of differentiating the eruptions of syphilis from non-syphilitic skin affections. [J. H. G.]

3.—H. H. Seabrook discusses the subject of headaches due to eye-strain which are explained by "direct mechanical" theories. Two forms of eye-strain are generally recognized as the cause of headache. They are the accommodative and ciliary-muscle strain from lack of proper glasses, and the muscular from the incoordinate action of the extrinsic ocular muscles in binocular fixation.

[T. L. C.]

5.—Charles R. Upson discusses latent pulmonary tuberculosis, using the term "latent" to indicate the unsuspected presence, in a large number of cases, of the disease. He believes that it is largely through ignorance of the true significance of the early subjective symptoms and the apathy of the lay population that the disease is permitted to gain such a firm hold on its victim. He suggests that the remedy lies in the publication and general distribution by boards of health of literature describing the early symptoms of pulmonary tuberculosis and the necessity whenever these described symptoms are observed of the examination of the lungs. [T. L. C.]

6.—E. W. Whitney calls attention to a manner of intensifying vibratory thrills in palpation. He suggests that the phonendoscope be placed on the chest and then, after removing the rubber tubes, the palmar surface of the hand laid upon the instrument and receives the vibrations which have been reduplicated. The action of the instrument is equivalent to that of a sounding-board. [T. L. C.]

MEDICAL NEWS.

July 20, 1901. (Vol. LXXIX, No. 8).

1. A Study of Sixteen Hundred and Fifty Blood Examinations for the Widal Reaction with Special Reference to So-Called Partial Reactions. ROBERT J. WILSON.
2. A New Method of Determining Approximately the Amount of Hydrochloric Acid in the Gastric Contents. MAX EINHORN.
3. Local Treatment of Female Diseases; Its Abuse. A. L. BEAHAN.
4. Disinfection Within and Without the Body in Diphtheria. M. A. VIEHNER.
5. Cerebral Apoplexy; Its Relation to Testamentary Capacity. CHARLES SCHRAM.
6. Surgical Diagnosis. JAMES J. McKONE.
7. Static Electricity in the Treatment of Sprain. LEONARD C. STANFORD.

1.—It J. Wilson gives a report of the Widal reaction. In the examination of 265 cases with the reaction, 46 were sent on or before the seventh day of the disease; 36 from the eighth to the tenth inclusive; 50 from the eleventh to the fourteenth day inclusive; 28 from the fifteenth to the twenty-first day inclusive; 7 from the twenty-second to the twenty-eighth day inclusive; 5 from the twenty-ninth to the thirty-eighth day inclusive, and in 93 the day of disease was not mentioned. In 34 cases the Widal reaction occurred upon the second examination of the blood; of these, 2 were negative on the third day and positive on the eighth and tenth days respectively; one negative on the fifth day and positive on the thirteenth day; one was negative on the sixth day and positive on the ninth day; 5 were negative on the seventh day and positive on the

eighth, ninth, tenth, thirteenth (2), fifteenth (2), and seventeenth days respectively. One was negative on the eighth and positive on the eleventh day. One was negative on the ninth and positive on the sixteenth day. Five were negative on the tenth and positive on the eleventh, twelfth, thirteenth, fourteenth and twenty-fourth days respectively. One was negative on the eleventh and positive on the fifteenth day. Two were negative on the twelfth and positive on the fourteenth and twenty-sixth days respectively. Five were negative on the fourteenth day and positive on the sixteenth (2), seventeenth, nineteenth and twenty-third days respectively. One was negative on the sixteenth and positive on the twenty-first day. Two were negative on the twenty-eighth day and positive on the thirty-fourth and thirty-eighth days respectively. One was negative on the thirtieth day and positive on the thirty-second day. One was negative on the thirty-fifth day and positive on the thirty-seventh day. [T. M. T.]

2.—M. Einhorn practices the following in Determining Approximately the Amount of Hydrochloric Acid in Gastric Contents: A minute quantity of stomach contents is placed by means of a glass rod upon a strip of dimethyl-amidoazo-benzol paper (one-half by eight centimeters). If the paper turns red one drop of the contents is diluted with two drops of water in a small porcelain dish. A glass rod is dipped into the mixture and the test paper again touched. If it still turns red, one or two more drops of water are added and the procedure repeated as before. This is done until only a slightly red or almost no red color is produced by the mixture upon the test paper. In this way the amount of dilution required for a trace reaction with the test paper is determined. It is clear that the more HCl there is in the stomach-contents the more they can be diluted, still giving a trace reaction with the dimethyl-amido-azo-benzol paper. [T. M. T.]

5.—C. Schram, in his article on Cerebral Apoplexy; Its Relation to Testamentary Capacity, gives Dr Gallard's opinion as follows: The aphasiac is (1) irresponsible if he cannot manifest his lucidity by words, pantomime or writing; (2) His intelligence is impaired, if he manifest his lucidity by words, pantomime or writing incompletely or sluggishly; (3) He is responsible if he manifest his lucidity and intelligence by words, pantomime or writing. Schram also considers the mental status in the various forms of aphasia. In the motor form uncomplicated there is least intellectual disturbance, supposed to be due to a lesion at the foot of the third left frontal convolution. Auditory aphasia is due to damage done to the posterior thirds and of the first and second convolutions of the left temporal lobe, resulting in word deafness. Visual aphasia is due to lesions of the angular gyrus of the left parietal lobe, is more serious in its effects on the intelligence than the auditory form. Finally, we have to consider verbal amnesia, which is the most serious form, leading to confusion of thought and diminution of intelligence. The lesion is found in the concept area of the brain, located by Wernicke in the convolution of the island of Reil. The condition results from the cutting off more or less completely of the connection nerve tracts between the concept area and the areas in which are stored auditory, visual and motor word memory centers. [T. M. T.]

7.—L. C. Stanford, in the Treatment of Sprain by Static Electricity, describes the method as follows: The electricity is generated from a Holtz machine of the largest size. The patient is placed on an insulated platform, which is connected with the negative pole of the machine by a brass rod. An electrode connected with the positive pole by a brass chain, gives off the spark after the circuit has been completed; the length of the spark being from two to four inches. The application is made over and around the painful areas by the positive electrode. The administration lasts from ten to fifteen minutes, and is occasionally broken by a short intermission. [T. M. T.]

1. The Cyst of the Omentum. A. JACOB
2. Some Remarks on Tetanus. FIELDING LEWIS TAYLOR.
3. Common Law Rights and the Physician's Prescription. J. WILKINSON JERVEY.

4. A Unique Case of Dupuytren's Contractions; Operation by the Open Method. FRANK E. PECKHAM.
5. A Case of Traumatic Rupture of the Intestine.

FREDERICK T. WRIGHT.

1.—Will be treated editorially.

2.—F. L. Taylor, in his *Remarks on Tetanus*, gives the following indications for treatment: (1) To remove the infection atrium, and so prevent the formation of more toxin; (2) To neutralize the poison in the blood; (3) To prevent the extension of the poison to the higher centers; (4) To quiet the cells already irritated; (5) To facilitate elimination. [T. M. T.]

3.—J. W. Jervy, on *Common Law Rights and the Physician's Prescriptions*, sums up the common sense and legal status of the physician's prescriptions as follows: (1) The patient has no legal nor other right to demand a written prescription or written directions from the physician, (2) It is right and wise that the druggist demand and procure from the physician his written orders for the compounding of prescriptions; (3) The physician has the undoubted right to designate what pharmacist shall fill his prescription; (4) The written prescription is simply an order from physician to pharmacist. It is, through courtesy, and by virtue of custom and convenience, handed to the patient for transmission; but the latter has not at any time, the slightest right of possession in the instrument; (5) The druggist has, at least, the right of permanent guardianship (perhaps of outright possession) of the prescription, and he must keep it on file for reference and for any form of proper investigation; (6) There can be no right, extenuation, or excuse for a copy of a prescription, with physician's name attached, to be taken by druggist, patient or any one else without the authority of the physician; (7) The careful physician should invariably retain on carbon paper facsimile copy of every prescription he writes; (8) The druggist has a legal right to utilize any formulae that is uncopyrighted that may fall into his hands, but he cannot, unauthorized, use the name of its author in connection with it. In most States, however, statutes would bar his selling intoxicants or other poisons except by direct order of physicians; (9) If a druggist refills a prescription without the order of the physician who wrote it, he does so on his own responsibility, and he has no legal nor moral right to leave or place the physician's name on the container. [T. M. T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

1. The Shattuck Lectures. The Alleged Increase of Cancer in Massachusetts. WILLIAM F. WHITNEY.
2. The Clinical Value of Some of the Newer Hypnotics. ALBERT E. BROWNRIGG.
3. Cases Illustrating Minor Surgery of the Kidney. JOHN BAPST BLAKE.
4. Advantages of Sanatorium Treatment of Pulmonary Tuberculosis. HENRI T. FONTAINE.

1.—William F. Whitney in his Shattuck lecture on the alleged increase of cancer in Massachusetts presents some interesting facts. A number of statistical tables are included in the article, showing the death rate and ratio of males to females from the disease. If death from cancer should go on at the apparent geometrical rate of increase of the past fifty years, in two and a quarter centuries every person over thirty years would die from that disease. This rate is probably only arithmetical at its worst. The increase is probably due to better diagnosis and registration, and until the ratio of deaths over thirty years has reached 8 to 9%, which is shown by autopsies to be the true rate for cancer, it is not justifiable to speak of the increase as inherent in the disease itself. For purposes of comparisons with other places or years, a graphic picture, composed of both the rate and ratio curves, covering the period over thirty years, divided into decades, is the best. Comparisons with other States and countries show the rate for Massachusetts to be about the same as theirs, with greater variations between the males and females than is the case in Austria, which is remarkable for the correspondence between the two sexes. In the distribution in the New England States, there is no geographical feature that explains the variations, which is easily within the limits of better registration. In the State itself there is slight increase westward for groups of counties of the same density of population. The densest

populated part of the State, apart from these, shows a little higher rate. [T. L. C.]

2.—Albert E. Brownrigg discusses the clinical value of some of the newer hypnotics. The paper deals with three synthetic combinations: amylene chloral, (dormiol), chloroform acetone, and hedonal, a derivative of urethane. [T. L. C.]

3.—John B. Blake presents clinical notes of four cases illustrating minor surgery of the kidney. In the first case nephrorrhaphy was performed. In the second case nephrotomy was performed for traumatic rupture of the kidney and recovery followed. The third case presented acute abdominal symptoms. Laparotomy was performed and an abscess of the kidney found. In the fourth case nephrotomy, resection of the kidney and nephrorrhaphy were the operative procedures. [T. L. C.]

16. Artesia Hymenalis, its Etiology and Treatment. O. THIENHAUS.
17. How Shall We Deal with Uterine Myomata? E. E. MONTGOMERY.

1.—Samuel W. Kelley discusses the advancement of surgical pediatrics. He goes very carefully into the literature of surgical diseases of children, showing that these subjects were not treated separately by surgical writers until recent times. In 1867 Holmes issued his work on "Surgical Treatment of Diseases of Children." Great stress is laid upon the fact that there is a difference between the surgical diseases of child and adult life just as there is between the medical ailments. It is thought that this subject is not given sufficient space in the curriculum of our medical colleges. [J. H. G.]

2.—Mackenzie delivered the annual address before the section on laryngology and otology at the 52d meeting of the American Medical Association. He discusses the importance of the study of laryngology and believes that it should hold a high place in the curriculum of medical colleges. He emphasizes that a thorough knowledge of the uses of the laryngoscope will be necessary to the equipment of the advanced physician of the future, and that this instrument is invaluable to the diagnostician. The greater portion of the address is given to the consideration of the development and the increasing general knowledge of laryngology and also to the methods of teaching this study in the Johns Hopkins Medical School. [F. J. K.]

3.—Carpenter states that it is very uncommon to find healthy gums, and that it is of frequent occurrence to find inflammation, hypertrophy, and ulceration of the gums.

gingivitis does not often result from bands, clasps, wedges, or ligatures. The most important causes are: imperfect contour and irregularities of the teeth; insufficient and improper use of the teeth; the use of dentifrice which contains inorganic substances; the careless and injudicious use of tooth-picks and rubber bands; improper nourishment; cachectic states; and the conditions which produce dyspepsia, constipation, sick-headache, and dyspnea may also give rise to gingivitis. He recommends the following treatment for gingivitis, the contour of crowns should be corrected and all irritants removed. Tincture of iodine should be lightly applied to the irritated surface. He also recommends cleansing the teeth and gums vigorously after each meal and before retiring, and suggests corn meal as a dentifrice. [F. J. K.]

4.—Hatch considers the subject of **military dental practice**, its modifications and limitations. He believes that prosthetic dentistry, orthodontia, crowns and bridge work, and gold filling are the branches of dentistry which should be eliminated altogether from military dental practice. The army dental outfit should consist of only such instruments which are consistent with good work, and should be snugly packed. He concludes the article with a discussion of the limitations of operative dentistry, to be assigned to the dental military surgeon. [F. J. K.]

5.—Marshall opened the discussion of **military dental practice**. He emphasizes that the passage of the Army Reorganization Bill with its sections creating the corps of dental surgeons for the United States Army, marks an important epoch which is destined to be far reaching in its beneficial results. The army dental surgeon will have the relative rank of a first lieutenant, and will be employed as a contract dental surgeon. His salary is \$150 per month with quarters. The Army Medical Department will furnish all instruments, apparatus, and materials for conducting the practice. The remainder of the address includes a consideration of the examination of candidates, assignments to duty, regulations governing dental corps, the equipments, and the system of keeping records. [F. J. K.]

6.—Fletcher states that the surface of the tongue offers a suitable soil for the development and growth of myriads of bacteria, because its irregular surface may be easily coated with pabulum. A number of the constituents necessary for the growth of micro-organisms are already present upon the tongue, namely: buccal mucus, saliva, particles of food, dead epithelium, and exudations from diseased gums. The author contends that the general consensus of opinion, in regard to the coatings of the tongue, is that they are not indicative of any particular disease, but simply of local significance. Too much importance cannot be placed upon keeping the mouth perfectly clean, for undoubtedly much fermentative and putrefactive indigestion will be prevented by such a measure. [F. J. K.]

7.—Hayard Holmes asserts that the difficulties of diagnosis cause the surgical diseases of the kidney to be neglected by the general practitioner. He then reports two very interesting cases illustrating the difficulty of diagnosis. The first case is that of a woman 35 years of age who presented at times a tumor in the region of the gall bladder. These attacks were accompanied by pain and vomiting and a slight temperature. The tumor moved with each inspiration and expiration and was tender to the touch. The tumor disappeared and with it the pain and other symptoms. At one time there was a slight jaundice and bile was present in the urine. The patient complained of pain in the back and shoulders. The urine was normal. When the abdomen was opened the tumor was found to be a cystic kidney in which the whole organ was involved. Nephrectomy was done and the patient made a good recovery excepting for a slight infection of the wound. The second patient was a woman, aged 40, who had had repeated attacks of colic with fever and jaundice. The greatest pain complained of was in the abdomen, back and shoulders and there was none in the leg or vulva. The pain came on suddenly and as suddenly disappeared. The urine was frequently examined and was normal. Finally in one of the attacks a distinct tumor could be felt in the gall bladder region. During one attack the patient's pain suddenly disappeared during palpation of the abdomen. Operation showed the gall bladder to be normal and revealed the presence of a floating kidney. This organ was fixed in its normal position and the patient has been free from suffering since. [J. H. G.]

8.—Henry P. Newman is of the opinion, as stated in an article entitled "The gynecological and obstetrical significance of girlhood," that the period between childhood and womanhood is at present not what it ought to be. The demands made upon the vital forces of the girl by the exigencies of modern educational and social systems, irregular meals, burdensome attire, all help to depreciate the physical standard of the present girl. He calls attention to the typical maldevelopment of the cervix as playing a disastrous role in the future of the woman. Mothers should be instructed in the management of maturing children and perfect confidence exist between the mother and daughter. The attire should be unconfined, forced mental development abstained from, and strict attention be paid to hygiene, sleep, diet and exercise. Various gynecological anomalies existing during the transition from girlhood to womanhood are discussed. [M. R. D.]

9.—W. S. Gottheil reports an interesting case of **adenosebaceous of the non-symmetrical type**. The patient was a girl 19 years of age. The growth was situated just above the temporal region, and presented a curved elongated patch $2\frac{1}{2}$ by $\frac{3}{4}$ of an inch in width. The surface was slightly elevated and a little rugose. At first this was thought to be a case of xanthoma. Examination, however, showed it to be an adenosebaceous. [J. H. G.]

10.—O. T. Freer, in discussing the treatment of laryngitis, begins with the treatment of the simple catarrhal type of the disease. Here cough is a prominent feature, and should be controlled by codeine. The inhalations of hot steam are of great advantage. Voice rest is absolutely necessary. The salicylates should be given internally in these cases. Menthol volatilized or sprayed in oily solutions, Freer has not found very satisfactory. This form of laryngitis usually responds promptly to treatment unless the voice is used. As the case advances nitrate of silver is strongly recommended, or what is perhaps better, protargol. This latter really does not cauterize, and penetrates tissues deeply. Stress is laid upon the fact that the oily menstrua inhibit the action of antiseptics. The spray is considered the best means of applying local treatment. The author refers to the advantage of using a tracheal spray tube devised by himself. In the acute submucous laryngitis local applications are of little advantage, since the trouble lies in the lymphatic channels which are not reached by the remedies. In fact, local applications may do harm in these cases. Pilocarpin administered by hypodermic is of considerable advantage. Occasionally the epiglottis is so swollen as to be immovable, and in such a case there is danger of fluids passing into the trachea. Under such circumstances it is advisable to feed the patient with a stomach tube. Acute hypoglottic laryngitis of adults produces a most distressing dyspnea requiring tracheotomy or intubation not infrequently. Laryngitis sicca, in which there is scabbing and crusting of the larynx, is greatly benefited by the inhalation of normal salt solution from a steam atomizer. The greatest advantage, however, has followed the use of the protargol spray. In hemorrhagic laryngitis tannic acid is indicated, together with cold applications to the neck. Finally the author describes the various forms and treatment of chronic laryngitis. [J. H. G.]

11.—J. S. Gibbs discusses **edematous laryngitis**, and reports a number of cases illustrating the condition. He concludes by describing several types of idiopathic edema of the larynx. First there are those cases in which there is no true inflammatory condition of the mucous membrane, but simply a transudation of serum into the submucosa. This condition is found in cases of far advanced nephritis with cardiac and vascular changes. Another type is that found accompanying acute catarrhal laryngitis. The condition may also be of an infectious or septic origin. The latter class of cases is frequent during epidemics of influenza. [J. H. G.]

12.—G. E. Cott reports a case of a 17-year-old boy in whom he removed nearly the entire thyroid because of pressure which it produced upon the trachea. [J. H. G.]

13.—Casselberry believes that the classification which attempts to differentiate the types of membranous pharyngitis by the sneezal micro-organisms which induce the infection is far from complete. The author gives a report of a case of pharyngitis due to the staphylococcus which so closely resembled the pharyngitis due to the diphtheria

bacillus, that antitoxin was given without waiting for the bacteriological report. On the third day, the membrane separated. A second report is given of a case of membranous pharyngitis due to the streptococcus and staphylococcus infection. [F. J. K.]

14.—L. H. Baker, in discussing the relation of the middle turbinate bone to chronic nasal affections asserts that this turbinate is much more frequently the cause of keeping up chronic nasal inflammations than is generally supposed. It is frequently the seat of polyps due to irritation of the discharges coming from the adjacent sinuses. This mucous membrane becomes swollen and hypertrophied, producing a blocking of the sinuses, thereby preventing free drainage. Frequently upon the removal of a polyp, there will be a gush of pus from the maxillary antrum. Under such circumstances the author urges that the whole turbinate bone should be removed, and not the polyp only. The author refers to two patients who died from cerebral involvement due to poor drainage of the nasal sinuses, and in which he thinks a removal of the middle turbinate might have prevented death. The author considers the fetid crusting of the discharges on the upper portion of the nasal chambers in non-specific patients an indication for the removal of the bone. "Bulbous hypertrophy" is also considered an indication for the removal of the bone. When the middle turbinate presses upon the septum, producing more or less severe symptoms, it should be totally removed. [J. H. G.]

15.—J. J. Goodale reports two cases of acute edema of the nasal septum. The condition closely resembles the edematous inflammations occurring in the soft palate. There is a marked constitutional disturbance and evidence of an infectious process. In the cases reported the mucous membrane of the naso-pharynx was generally inflamed, but the edema was confined to a limited portion of the nasal septum. It presented in both of these cases a large translucent pedunculated mass resembling closely a mucous polyp. The duration of the process was from two to three weeks. In each case the growth was examined microscopically and found to present the appearance of an acute inflammatory edema. [J. H. G.]

16.—O. Thienhaus, in discussing atresia hymenalis, its etiology and treatment, comes to the following conclusions: 1. The origin of gynectresias in a simple genital tract may be two-fold: a. caused by an inflammatory process, which is true in the majority of cases; b. caused by congenital malformation, as shown by Van Tussenbroek. In a case of atresia hymenalis, which, however, can find, as above cited, another explanation, and by Landau in a case of atresia cervicalis produced by a mesonephric fibroid. 2. The practitioner must pay attention to every case of birth where he suspects a gonorrhoeic infection of the maternal genital tract, not only to the eyes of the new born, but also in the same manner to the vulva and vagina; and, if he finds an infection of these parts he should treat them carefully with .5% of protargol solution three times a day, as advised by Siebert, or by other methods. 3. In all infectious diseases during childhood possible inflammation of the genital apparatus must be taken into consideration. 4. The physician must enforce a thorough examination in all cases of molimen menstruale with absence of menstrual flow. 5. If he finds an atresia somewhere in the general tract as the underlying cause, he must not cut blindly into the hematocolpos or hematometra, but must direct his method of treatment after the question: Is there hematosalpinx present or not? 6. If the latter is diagnosed, laparotomy must be performed first, and then the hematometra or hematocolpos opened by the vaginal route. [W. A. N. D.]

17.—E. E. Montgomery, in considering the question "How Shall We Deal With Uterine Myomata," believes that from our knowledge of the progress of these growths we are justified in answering the question as follows: 1. Small uterine myomata, which do not give rise to symptoms, are subperitoneal or interstitial, and may be permitted to go untreated, but the patient should be kept under observation, and any increase in size should indicate operation, as continuous growth may result in destruction of the uterus. 2. Small growths which cause hemorrhage are submucous or interstitial, and should be removed through the vagina. They can be made accessible by tents, or by incision through either the anterior or posterior lip. 3. Multiple growths, or small growths, non accessible by

the vagina, which cause symptoms, could be removed by abdominal incision. The uterus should be preserved whenever practicable. 4. When the growths are large, or when extirpation of the uterus necessary, the entire removal of the organ, as described in the text, is the simplest and most expeditious procedure. [W. A. N. D.]

AMERICAN MEDICINE.

July 20, 1901.

1. A Review of the Progress of Therapeutics for the Preceding Twelve Months.

REYNOLD WEBB WILCOX.

2. Pneumotomy for Abscess of the Lung, with Exhibition of Patient. W. JOSEPH HEARN and W. J. ROE.
3. On the Evils Arising from the Failure to Recognize the True Nature of Neurasthenia, and Some Causes of this Failure. W. W. JOHNSTON.
4. Anesthetization as a Specialty: its Present and Future. S. ORMOND GOLDAN.
5. The Relation of Pharmacists to Physicians, and the Relation of Pharmacy to Materia Medica and Drug Therapeutics. F. E. STEWART.
6. Foreign Bodies in the Rectum, with Report of a Case. LEWIS H. ADLER, Jr.

7. Removal of Ovarian Cyst, Broad Ligament Cyst and Appendix at the Second Month of Pregnancy; Delivery at Term. MAURICE KAHN.

1.—R. W. Wilcox, in the presidential address delivered before the American Therapeutic Society, reviews the progress of therapeutics for the preceding 12 months. The progress made in internal antisepsis is mentioned, as well as the Corning-Bier method of producing anesthesia by cocaineization of the spinal cord. The electrical light bath is discussed, the Flinston light treatment and the Röntgen rays. The action of sodium cacodylate, adonidin digitalin and digitoxin are also mentioned, as well as serum therapy and organo therapy. An urgent plea is also made for drug standardization. [T. J. C.]

2.—W. J. Hearn and W. J. Roe report an interesting case of pneumotomy for abscess of the lung. After giving a brief history of the operation and the improvements made in the operative technique, the authors give a minute account of their patient, who was a young man 24 years of age. The patient's lung trouble dated back to his third or fourth year. When he first applied to the authors for treatment he was suffering from a large abscess in the left lung which emptied itself through the trachea. Repeated explorations of the lung were made without revealing the abscess. Finally, however, the abscess was located in the lower back part of the lung, and found to have opening into it two bronchi, into which a probe could readily be passed, producing severe paroxysms of coughing when it reached the trachea. The abscess was drained by means of a tube. The patient improved after the operation, but required daily irrigation because of the excessive discharge and its foul odor. Palladium bichloride solution was found to do more toward lessening the quantity of pus than any other remedy employed. Permanganate, pyoktanin and formalin solutions could only be used for a few days because of the irritation which they produced. Colored solutions introduced through the tube could be readily coughed up by the patient. During the two years following this operation the patient continued to improve in general health, but the discharge from the abscess cavity continued profuse and very offensive, causing the patient to beg that something further be done. Ether was administered, a portion of the abscess was excised, and its margins sutured to a large opening made in the chest wall. Great local improvement followed this operation, there being no longer a necessity for irrigation or the wearing of a drainage tube. The discharge, however, continued, but there is no longer the horribly offensive odor which was so distressing to the patient. At no time were tubercle bacilli found either in the pus or in the expectoration. The authors think this abscess to have been the result of a localized gangrene of the lung. No difficulty was observed in the administration of ether in any one of the many instances in which it was employed, nor was any difficulty encountered from the daily irrigation through the drainage tube when that was employed. [J. H. G.]

3.—W. W. Johnston presents a paper on the evils arising from the failure to recognize the true nature of neurast-

thenin, and some causes of the failure. He cites the case of Charles Darwin, which includes every essential fact necessary to show the evil arising from the failure to carry out a proper treatment of neurasthenia. Johnson mentions the hindrance to prompt and thorough treatment of neurasthenia in the general want of appreciation of its symptoms among young medical graduates, and believes there is a great opportunity in this country for the development of the treatment of neurasthenia in institutions properly conducted. [T. L. C.]

4.—S. O. Goldman, in writing upon **anesthetization as a specialty**, discusses the present and future status of the anesthetist, showing the great responsibility of his position and devoting considerable space to the question of fees. [J. H. G.]

5. See the **Philadelphia Medical Journal**, May 11th, 1901 [T. L. C.]

6.—L. H. Adler reports an interesting case in which a man 60 years of age, a machinist, passed into his rectum the handle and valve of a steam radiator pipe. The diameter of the smaller end of this foreign body was 1½ inches and of the larger end was 2½ inches. From a history obtained from the patient's son and his attending physician, it seems that the patient had been in the habit of introducing this foreign body into the rectum and extracting it by means of a specially made hook. The extraction of the foreign body was accomplished after long and tedious efforts. [J. H. G.]

THE JOURNAL OF NERVOUS AND MENTAL DISEASE.

June, 1901. (Vol. 28, No. 6.)

1. A Case of Bullet Wound in the Spinal Cord; Operation three years later. JOSEPH SAILER.
2. The Rationale of Subjective Healing. SMITH BAKER.
3. An Anomalous Case of Paralysis and Dystrophy of Muscles Probably Dependent Upon Both Neural and Spinal Lesions. F. X. DERCUM.
4. Notes on a Remarkable Case of Insomnia and Its Treatment. JOHN E. BEEBE.

1.—Sailer reports a case of **Bullet Wound in the Spinal Cord** in which the interesting features were, (1) Localization of injury in spinal cord; (2) Satisfactory results of the operation three years after receipt of injury; (3) The curious sensory phenomena (talochiria) shortly after operation while improvement was still in progress. [T. M. T.]

2.—Baker in summing up his article on the **Rationale of Subjective Healing**, comes to the following conclusions: (1) The final unsatisfaction of diagnosing, if never so accurately, the special affection alone, and not at the same time giving heed to the entire individual in whom it is found. The time has already seemed to come when we should go to the modern psychological and pathological laboratories and there learn that the human being is neither mind nor matter alone, but that in every feeling, thought and act there is a unified energizing, of which mind and body alike are necessary concomitants; (2) The utter uselessness of wearing out people with multitudinous remedies, of no matter what order, that are aimed only at symptoms; and, likewise, the harm which may be done in thus cultivating unneeded for dependence upon just such supports. One need not be an extremist, or a skeptic, to see the absolutely scientific injustice of this; (3) The danger of extreme concentration of a purely subjective order, and of the psychical elation which has not been given a corresponding solid basis to sustain it. It cannot be said that any such exclusive devotion to one aspect of life, is very generally developmental or safe, in the long run. What most of these people need is a clean, new set of mental images to be derived objectively rather than concentered from, no matter how intense, subjective application; (4) The inadequacy of even a good initiation, when subsequent developments are defective or counteracting. The "healer" often seems to make a good start and in the right direction, so far as the particular individual is concerned. But his lack of physical and pathological culture, to say nothing

of the theological and psychological atavism which possesses him, robs the patient of that further restoration and development of mind and body alike, which he so universally needs; (5) Unless the body has been remedied, the mind furnished and stayed, and the conduct ordered in accordance with actual needs comprehensively estimated, no cure worthy the name can be expected from either materialist or idealist; (6) That neurologists and psychiatrists should proceed at once, to determine how far results, which are now secured haphazard and irresponsibly, can be gained by scientific inquiry and practice. This is needed, if for nothing more, than that medical education and practice may receive a proper impetus and backing in this much-needed direction; (7) That people, especially when young, should be encouraged to most sedulously cultivate bodily endurance, mental growth and freedom, moral heroism, and spiritual self-reliance, faith in inductive science, rather than trust in dogmatic deduction; all in the hope, that where now there is such a readiness to develop morbid introspection and fears, imperative conceptions and mental shiftlessness, there shall be achieved a commendable flexibility and direction of mind, and the possibility of a joyous overcoming of ordinary obstacles. [T. M. T.]

5. The Treatment by Koumiss and Some Koumiss Settlements in the Government of Oufim. P. V. TSEZAREVSKI.

1.—Treated editorially.

2.—Popelski directed his attention to the fact that pilocarpine exerts a stimulating effect on the salivary and other superficial glands, but its action on the deep-seated glands, such as the gastric or pancreas, is either altogether absent or very inconstant. In seeking an explanation to this phenomenon, he found that by injecting pilocarpine into the circulation of a cat and at the same time stimulating the pancreas by some irritant, he could cause a free flow of the pancreatic secretion. Such an irritant to the gland is supplied by hydrochloric acid 0.4-0.5% introduced into the small intestine either artificially or in the course of normal digestion. The explanation offered is that pilocarpine can act on the glands only when the latter are stimulated by external irritants to physiological activity, the effect of the drug being to heighten the excitability of the terminals of the secretory nerves. In the case of superficial glands external irritants are as a rule always present, and, moreover, their inhibitory apparatus is much weaker than that of the deep-seated glands. [A. R.]

5. The Treatment of Koumiss and some Koumiss Settlements in the Government of Oufim. P. V. TSEZAREVSKI.
6. On the Question of Reforming the Suvoroff School at the Kalkin City Hospital in St. Petersburg. P. E. OHOZHENKO.

1.—Will be abstracted when concluded.

2.—Will be abstracted when concluded.

3.—Vinokuroff observed two cases of complete rigidity of the spine resulting from spinal meningitis which developed in the course of convalescence from typhoid fever. (In one case the existence of typhoid fever is only pre-

sumed). In one the disease became chronic, and muscular atrophy supervened; in the other the meningitis did not advance beyond the acute stage, and muscular atrophy, as well as paresis, was absent. The following conclusions were reached: 1. "Stiffness of the spine" (*odererweitert*) is one of the conditions associated with cerebro-spinal meningitis. 2. The location and extension of this condition depends on the location and extension of the inflammation of the spinal meninges. The assertion of Bechteroff that the morbid changes take place at first in the cervical and dorsal portions of the spinal column is not well founded for in the above cases the affection commenced from below. 3. The paralytic state and atrophy of the muscles occur only when the underlying meningitis passes into the second or paralytic stage. 4. Kyphosis also appears only in the paralytic stage, and, seen in the second case, may be absent altogether, although the disease lasted for four years. 5. Similarly, anesthesia may be either slight or altogether absent. 6. The opinion of Bechteroff that the stiffness of the spine is simply the result of the kyphosis is contravened by the observation that kyphosis may be absent. The stiffness appears in the first stage of irritation, while kyphosis is of myopathic origin and can only occur during the paralytic stage. 7. The causes of "stiffness" are the same which produce the meningitis, viz., cold, trauma, infectious diseases, syphilis, alcoholism, diseases of the lungs, heart and liver. It may also be the result of rheumatism. 8. It is improper to include all cases of immobility of the spine into the group described by Bechteroff. The distinction between the various forms should rest on the pathologo-anatomical changes, and not on the symptoms. [A. R.]

4.—Brustein, after reviewing the literature on injuries caused by the electric current of high tension, reports the case of a man, 39 years old, who, while working on an electric transformer standing on a perfectly dry floor, received a shock of 3000 volts with 100 interruptions per second. He lost consciousness for 20-30 minutes, when he was able to get up and walk to the carriage. For about two months he was treated for the burns which he received, and recovered sufficiently to resume his work. Soon after he developed a neurosis associated with hysteria and neurasthenia. He presented a concentric narrowing of the field of vision, clonus of the patella, irregularity of the pulse, increased reflex action and muscular irritability, vasomotor disturbances and weakness of the extremities; in other words, this was a typical case of traumatic neurosis developing several months after the injury. The patient finally recovered under bromides, massage and electricity.

CENTRALBLATT FUER GYNAEKOLOGIE.

February 2, 1901. (No. 5).

1. Extirpation of a Right-Sided Ovarian Cyst Through a Left-Sided Inguinal Incision.

LEOPOLD REINPRECHT.

2. Case of Precipitate Labor. WILHELM KUNZE.
3. On the Treatment of Incarcerated Retrodisplaced Pregnant Uterus. L. SEELIGMANN.
4. A New Method of Protecting the Perineum.

J. HOFBAUER.

1.—Reinprecht reports a very interesting case of a patient presenting an ovarian cyst which was removed through an incision in the left groin, the cyst springing, however, from the right ovary. The patient was 65 years of age who menstruated first when she was 16 years old. Her menses were always regular and she had given birth to 4 children followed by normal puerperia. When 40 years of age the patient experienced the menopause. For 16 years before the operation she suffered from bearing-down pains in the abdomen, and for 1 year from severe left-sided abdominal pain, most marked in the inguinal region. For 3 years she had suffered from dragging and pressure in that region and had discovered a tumor the size of a hen's egg, which gave rise to some difficulty in urination. It was this pain in urination which brought the patient to the clinic. Examination showed an appreciable resistance over the right Poupert's ligament. A cystocele the size of a hen's egg was also present. The vagina was short, the portio small and undergoing senile changes and the cervix lacerated bilaterally. In front of the uterus and to the right a tumor was found the size of a fist, the uterus itself being retroverted. The parametrium was free, and the

adnexa could not be felt. There was also a left-sided inguinal hernia. The diagnoses were left-sided inguinal hernia, a tumor resembling a right-sided ovarian cyst, cystocele, and an old incomplete peritoneal rupture. The operation was performed primarily to relieve the hernia, and an incision was made and Haslani's operation performed. Before closing the wound, however, an examination was made intraperitoneal, the tumor palpated and the incision enlarged a little in order to extract the cyst after puncture. About 400 ccm. of a greenish fluid were removed. The cyst was then drawn out from the wound, its pedicle ligated and fixed in the lower extremity of the womb; the peritoneum was closed and the muscles united by means of 6 celluloid sutures. This operation was followed by an anterior kolporrhaphy and a restoration of the floor according to Lawson Tait's method. [W. A. N. D.]

2.—Kunze records an interesting case of premature labor in which the child was born almost without any labor whatever. Delivery was accomplished as he entered the corridor of the house, and on reaching the room he found a loudly crying new-born child lying upon its back in a large puddle of slightly stained liquor amni. The child had been born so quickly that the umbilical cord had been drawn out of the abdominal wall. No hemorrhage had taken place from the site of rupture. The end of the cord hung from the birth-canal. The woman had immediately taken to her bed upon the birth of the child. The child breathed well and strongly and showed no signs of injury resulting from its precipitate delivery. The labor was but 8 minutes long. The child showed all the signs of maturity. It was 50 cm. long and the circumference of its head was 34 cm. The cranial diameters were normal. There was no caput succedaneum. The measurements of the woman's pelvis were on the other hand below normal. The distance between the anterior, superior iliac spines measured but 23 cm. Between the crest $25\frac{1}{2}$ cm. and the external conjugate 19 cm. The length of the umbilical cord remaining attached to the placenta was 25 cm. The mother was 24 years of age and in her second pregnancy. The puerperium was quite normal. The interesting feature in this case was the precipitate labor in an undersized justo minor pelvis. [W. A. N. D.]

3.—Seeligmann refers to a paper written by Dührsenn in 1898 on the subject of the treatment of backward displacement of the pregnant uterus with incarceration under the sacral promontory. He then describes the case of a woman 35 years of age who had become pregnant in a retroflected and fixed uterus, the abnormal position resulting from a chronic perimetritis. He was able to restore the uterus by a process of treatment which he describes as follows: In cases of uteri which are backward displaced with their long axes lying in one of the oblique diameters of the pelvis he makes energetic traction on the portio with one hand while at the same time moderate pressure is made upon the fundus uteri toward the normal position. Usually it will be found that the pressure may be best made from the right side posteriorly toward the left on account of the position of the rectum toward the left side. The uterus having been partially restored in this manner a kolpeurynter filled with fluid is placed under the displaced fundus uteri to that side toward which the uterus is directed. The constant pressure made by the kolpeurynter will tend to restore the uterus to its normal position. After 2 or 3 hours the kolpeurynter may be withdrawn. Subsequently the treatment may be repeated as required. [W. A. N. D.]

4.—Hofbauer questions which is most advantageous, the patient resting on the back or in the side position, in the protection of the perineum during labor. He remarks that particularly in primiparae the preference is generally given to the side position. The author gives a review of the mechanism of labor and speaks of the various methods of perineal preservation. He describes a method which he has adopted, in which the right hand rests flat on the perineum so that the frenulum remains open to inspection. When the tension of the perineum becomes great, especially when the posterior margin of the larger fontanel begins to pass the perineum, the head is twisted in such a manner that the hand which grasps around the head from backwards is brought into the oblique diameter. The twisting may reach to 40 degrees, and may be performed to the right or to the left. The tense perineum is thereby relieved and the sides of the vulvar orifice become stretched. The emergence of the head is thereby facilitated and delivery will probably be accomplished without laceration. [W. A. N. D.]

1901. (Volume 63, No. 2.)

10. Habitual Luxation of the Patella. WILHELM FRIED LAENDER.
11. Small Caliber Rifle Wounds from the Experience of Recent Campaigns. HEINRICH MOHR.
12. Tumors of the Fingers. ROBERT F. MUELLER.
13. Necrosis by Schleich's Anesthetic Mixtures. F. SELBERG.
14. Inflammatory Tumors of the Omentum. HEINRICH BRAUN.
15. Some Contributions to Lung Surgery. FR. BORCHERT.

10.—Luxation of the patella is traumatic, congenital, or pathological. Traumatic luxation, when not treated, tends to become habitual. Congenital luxation may also become habitual, in the later years of life. Pathological dislocation of the patella is generally habitual. Friedländer reports cases of congenital dislocation of the left patella, and double pathological dislocation. The first was seen in a girl of 12, with dorsal scoliosis and decided deformity of the thorax. Accidentally, luxation of the left patella was discovered, which had never caused any trouble. She only noticed that it slipped out of place on rapidly running down stairs. With extension, it always slipped back into place. The internal condyle on the left leg was noticeably more prominent than on the right, the external condyle being markedly flattened. On bending the left knee, the patella rotates outward, causing a projection to the left side of the knee. The second case occurred in a girl of 12, who had double congenital dislocation of the hips until 5 years of age. Following operation, ankylosis of both hips resulted, so that standing and walking are very difficult. Only this year was the double luxation of the patella noted. Her brother, six years older, had had the same operation performed for congenital dislocation of one hip, with resulting ankylosis and luxation of the patella of that leg, later. The ankylosed hips stand at an angle of 20°, and there is slight compensatory lordosis. The luxation of the patella occurs whenever the knees are bent. The knee joint looks flat. With extension, the patella returns into place. In these cases the dislocation is outward, as is most common. The tendency toward the "knock knee" position in girls is considered a cause of the luxation, as is traumatism in men. It is also due to changes in the configuration of the ends of the bones forming the joint, and to an enlarged and flaccid condition of the joint capsule. Neither rachitis nor heredity have any influence etiologically. But in the second case a congenital disposition to luxation of the patella existed, probably aided by the changed muscle action due to the ankylosis of the hip-joint. The prognosis of untreated cases is bad. Massage, gymnastics, and bandages may aid, but operation will probably still be necessary. Friedländer advises Hoffa's modification of the Le Dentu operation in both cases. A table of the 43 cases of habitual outward luxation of the patella collected, follows. [M. O.]

11. There is now a concurrence of general opinion in the belief that the modern small caliber rifle is much less dangerous to human life than any gun formerly used. The larger the caliber, the more deadly is the effect upon the enemy. Deflected, ricocheted bullets do more harm than primary shots. Mortality has decreased 50%, and a much less number are chronically invalided. The wounds are clean cut, depending upon the distance from the shot. Fewer bullets remain in the body, and these are harder to extract than formerly. The surrounding tissue is but little damaged. The nerves are much less frequently injured, and paralysis is rare. Shock may, however, be severe. Hemorrhage from injury to large blood vessels is seldom seen, and immediate operation is often followed by recovery. Primary infection is now very rare, but secondary infection occurs, during transport, etc. When infection appears, nowadays, it remains localized to the external wound. Pyemia and tetanus follow very rarely.

To prevent infection is the main treatment at first. Aseptic and antiseptic dressings are employed universally. Intercurrent disease often causes extremely retarded healing in cases of gunshot wounds. Operations are much less frequent than they were. Only when infection occurs is immediate extraction of the bullet considered necessary. Immediate death followed bullet wounds of the heart, in spite of three cases operated. But in four, out of five cases of wounds of the pericardium, which came to operation, recovery followed. Wounds of the chest and abdomen were in many cases followed by spontaneous recovery, especially intestinal wounds. Gunshot wounds of the bones and joints showed remarkable freedom from infection. Wounds of the spinal column generally proved fatal. The worst wounds were those of the skull, yet immediate modern treatment effects some good results. But infection occurs quickly in these cases. The Röntgen apparatus has been of great assistance in finding bullets and fractures. Bombs produced fatal wounds, with the exception of the lyddite bombs, which did little harm. A greater number of instant deaths followed infantry shots than formerly; but this was not true of the artillery. A vast mass of detailed statistics has been compiled by Mohr in this article. [M. O.]

12.—During a year's observation, Müller could find but 16 tumors of the fingers. Of these, 11 were seen in the Poliklinik, where 19000 cases came during the year. He reports these sixteen cases, of which two were lipomas, one on the middle finger of an old man of 72, and the other on the index finger of a baby under two years. The former had existed 6 years, the latter 16 months, and was possibly congenital. One was a mucous cyst of the index finger, and there were four ganglions on different fingers. The next two cases were tumors of cellular tissue caused by a thorn, and a piece of a needle. In neither case did the process go on to suppuration. The foreign bodies were encapsulated by cicatricial tissue. Six cases were pigment containing fibrosarcomas of the sheath of the tendons, with giant cells. The last case reported was a subungual perithelioma, which had existed 23 years. All the cases except the four ganglions were operated, with histological and microscopical examinations of the tumors removed. [M. O.]

13.—Selberg reports the results in 175 cases in which Schleich's anesthetic mixture was used. A useful anesthetic must be safe, and as pleasant as possible for the patient; it must be practicable, must keep, and must not be overly expensive; and it must produce complete anesthesia. It was prepared according to Schleich's directions. The average amount used, (from 22 laparotomies), was 2.85 c. cm. of the mixture per minute. There was very little excitement noticeable among the patients while being anesthetized. It was noted that there was no secretion of mucus, as is the rule with ether. Selberg concludes that the patient recovers more easily than from chloroform; that there is less pain after it than after ether or chloroform; and that the patient seems in much less danger during anesthesia. But it is harder to put the patient asleep; he is more disposed to complications afterward; and the administration of the mixture is peculiar. Unfortunately it is not the ideal anesthetic. [M. O.]

14.—Braun has in the last year observed 5 cases of inflammatory tumor of the omentum, which was neither epiploitis due to resection of the omentum, nor an infiltration with torsion of the omentum, following appendicitis. In all 5 cases, following an abdominal operation, a small tumor appeared, gradually increasing in size. Upon rest and moist bandages it gradually disappeared. In the last case he operated, excising a piece of the tumor, which was pure connective tissue with fat. All four recovered slowly. These inflammatory tumors of the omentum generally follow laparotomy. Braun has collected 30 cases in all, 21 of which followed laparotomy. They may appear after silk or cat-gut has been used, which had not been perfectly sterilized. They come on some time after the operation, from a month to three years. Pain appears first, some

for it, then the gradual growth of the tumor. It is generally found high up in the abdomen. Potassium iodide and mercuryunctions will aid its absorption. The 25 other cases collected follow in detail. [M. O.]

15.—Borchert reports 29 operated cases of lung disease, in 21 of which the affected part was itself surgically treated. The others were cases of empyema. The great majority of the cases were chronic inflammation of some sort. Some were degenerated cavities, which showed no tendency to heal upon internal treatment, accompanied by suppuration and necrosis; in others was bronchiectasis with ulceration; but most cases were abscesses of the lung. Operation is necessary when there is danger of pyemia, septicecemia, or hemorrhage. Or, when a great amount of pus with lung substance is expectorated, operation is indicated. Tubercular cavities should, however, not be operated, and when tubercle bacilli occur in the sputum, surgical interference is contraindicated. Thus far no tumor of the lung has been diagnosed early enough to attempt operation. Echinococcus cysts, when diagnosed, should also be operated upon. Actinomycosis of the lungs and pleura has already come to operation. The exact situation of the process existing, its limits, the fact that the same process exists in no other part of the same lung, and the diagnosis of its character must all be determined before operation. The character of the sputum, its amount, the presence of tubercle bacilli, lung tissue, elastic fibres, pus, etc., will be of great assistance in diagnosis. In these cases too much must not be expected from percussion and auscultation. Exploratory puncture will often aid, as will Röntgen photographs. Operation will be divided into two parts, going through the thorax and pleura, and opening the lung, pneumotomy. If empyema exist, that is first opened and drained, then pneumotomy follows. The pathological process is then removed, and the lung left open. The pleura can be sutured whenever there is danger of air entering, or to induce pleural adhesions. Hemorrhage is easily controlled; pneumothorax, dyspnea, and cyanosis occur rarely. Drainage is kept in for some time after operation. Healing occurs by granulation, filling up the fistula gradually from below. To facilitate expectoration, the fistula must at times be plugged. The histories of 30 operated cases follow, 3 of which were gangrene, 6 bronchiectasis, 12 abscess, (9 with empyema), 8 empyema alone, and 1 cancer. Death followed in 14 cases. The operations are described in full. Borchert concludes that operation is justified in acute or chronic cavity, when not tubercular; bronchiectasis; and abscess of the lung, with or without empyema. [M. O.]

MUENCHENER MEDICINISCHE WOCHENSCHRIFT.

May 21, 1901. (No. 21.)

1.—Lanz not being entirely satisfied with Kocher's method of treating the stump of the appendix, has tried angiothrypsy with the idea that perhaps he would secure

more satisfactory results. The objection to Kocher's method is of course that it requires considerable time, and that the occlusion of the lumen of the appendix is necessarily somewhat imperfect. By the crushing method the occlusion is necessarily complete, and the operation can then be terminated by invaginating the stump and fastening the serous surfaces together by a Lembert's suture. He has employed this method in about 100 cases with excellent results. [J. S.]

2.—Krumm, in view of the fact, that in some cases where it is necessary as a result of tumor or other form of occlusion of the common duct to unite the gall bladder with part of the gastro-intestinal tract, the operation of election, that is anastomosis with the duodenum, is impossible, discusses the advisability of anastomosis with the stomach itself. He reports the case of a man 57 years of age, who developed intense icterus with great distension of the gall bladder. A diagnosis was made of pancreatic tumor, and an operation was performed. This confirmed the diagnosis, and also showed the impossibility of a cholecysto-duodenostomy. The gall bladder was accordingly united to the stomach, an operation that was rendered more difficult by the difference in the thickness of the walls of the two structures. It was, however, satisfactorily accomplished, and the patient recovered very successfully. Seven weeks later death occurred as the result of progressive cachexia and a carcinoma of the head of the pancreas was found with secondary growths in the liver. [J. S.]

3.—Von Marschalko, in discussing the results of the Congress for the prophylaxis of venereal diseases, lays down certain principles that he believes indicate the proper direction in which reform should be instituted. In the first place he does not believe that any drastic laws will be effective; the only result will be an increase of clandestine vice, or at least such a degree of opposition on the part of the populace that they will, of necessity, be repealed. In the second place, he does not regard the present methods as at all efficient. He therefore suggests that the whole thing be modified and altered, and that more attention should be paid to instruction in individual prophylaxis. [J. S.]

4.—Saenger has performed a number of experiments with the object of determining to what extent liquids in a fine spray can be thrown into the larynx. He found that solutions of methylen blue taken into the throat or nose at the same moment as an inspiration, were deposited almost exclusively upon the posterior wall of the pharynx or in the nostrils. He then performed a series of experiments with glass tubes bent in various ways, and found that in all cases a single bending at an angle of 110° was sufficient to prevent the further progress of the liquid. A rubber tube was substituted for this, with practically the same results. A further series of experiments were therefore made in order to determine to what extent dry powders could be injected into the larynx. Glass tubes were taken, bent slightly, the inner surface covered with moisture by allowing water to run through them for several minutes, and then the powders injected at one end whilst aspiration was being performed at the other. It was found that in glass tubes bent 10 times at an angle of 110° no trace of powder could be found behind the 6th or 7th corner. He concludes that we cannot accept the inhalation of liquids in a finely divided state even when they are found in the bronchi and aveoli after death, because it is quite possible that they are inspired in the form of drops and reach the glottis. Even if small quantities are inhaled they are so minute that they can be of no practical value. [J. S.]

5.—Adler discusses the various forms of hereditary degeneration. He includes among these states of depression somewhat varied in character, usually associated with nervous constitutions. More serious than these is a general depression of a psychical resisting power. This is characterised by extreme reaction to slight stimuli, either in the

form of anger or grief, etc., diminution of intelligence after moderate debauches and rapid exhaustion of the ability to work. The next degree is a morbid increase in the susceptibility to certain impressions. As a general manifestation of these he mentions imperative conceptions or obsessions such as the fear of high places, or sharp instruments, the irresistible impulse to touch objects, etc. Many of these patients become so profoundly interested in questions of relative insignificance that they are unable to pay attention to other things. Still more serious forms are circumscribed mental or intellectual defects, periodic melancholia, periodic mania, and finally circular insanities. Finally we have hebephrenia, brachyphrenia, paranolia, and in the last stage imbecility or idiocy. He also divides the hereditary conditions into those with defects in the functional, in the nutritive, and in the constructive parts of the body. Among the functional conditions he includes all defects in intellect; among the constructive, the morbid formations of the brain and spinal cord, and among the nutritive, precocious senility of various parts, of actual degeneration as in muscular dystrophies. [J. S.]

6. Schmidt reports an interesting case. A man of 60 injured his finger and had blood poisoning. On admission to the hospital he refused to submit to amputation and returned to his home where he came under Schmidt's care. At this time there was a phlegmonous infiltration of the entire arm extending to the shoulder, with areas of circumscript gangrene. Free incisions permitted the evacuation of a considerable quantity of pus; the spread of the inflammation ceased, and the patient finally recovered with good use of the arm except where a scar, as the result of the gangrene, slightly limited the extension at the elbow. He regards this case as a brilliant confirmation of Dörfler's views. [J. S.]

7. Wittlauer reports a case in which a woman was entirely unconscious of the process of birth, and the child, in consequence, fell into a chamber vessel and was killed. There was no possibility of a pre-conceived act. [J. S.]

8. Salm describes a small apparatus designed to keep two hypodermic syringes with needles constantly in alcohol, so that whenever used they will be perfectly sterile. The apparatus consists essentially of a small cylindrical bottle with a screw top; in this is placed a small rack holding the syringes and needles. Beneath the lower part there is a coiled spring so that when the top is tightly screwed down the syringes are held firmly against it and no injury is possible. The alcohol which Salm regards as the most available liquid, may be replaced by any other antiseptic, at the wish of the physician. [J. S.]

9. Hirsch continues his discussion of the acute yellow atrophy of the liver, and reports a case that came under his observation, occurring in a woman 28 years of age, who was brought to the hospital with intense jaundice and reduced area of liver dulness. The history was that of jaundice which lasted for 6 weeks, and there had been loss of power and frequent attacks of fainting. Fever did not occur until the 9th week of the disease, and death at the end of the 10th. At the autopsy the characteristic changes of acute yellow atrophy of the liver were found, with beginning atelectatic pneumonia. Careful examination of the liver showed numerous areas in which the liver cells were arranged irregularly. The most important changes were the extraordinary numerous proliferated biliary ducts, which were found chiefly in the connective tissue. In a few cases proliferation of the parenchymatous cells of the liver could also be observed. These marked degenerative changes probably occurred as a result of the prolonged course of the disease. [J. S.]

CENTRALBLATT FUER INNERE MEDICIN.

April 27, 1901.

1. Investigations Concerning the Dialysate of Digitalis Grandiflora. SCHWARZENBECK.

1.—Basse has previously reported that the dialysate of Digitalis purpurea produced marked improvement in car-

diac symptoms, increased the diuresis notably, and was well borne by the stomach. Schwarzenbeck has investigated the clinical value of the dialysate of the digitalis grandiflora, and presents a series of case histories which show good results on the cardiac symptoms, the digestive organs, the respiration and the secretion of urine. Its prolonged use, however, like that of the usual preparations caused symptoms of cumulative action. He believes that the action of digitalis is chiefly due to the digitoxin which it contains. [D. L. E.]

ZEITSCHRIFT FUER HEILKUNDE.

May, 1901. (Volume 22, No. 5).

1. Secondary Infection in Pulmonary Tuberculosis. ALEXANDER VON WEISMAYR.
2. The Study of Poisoning. ERNST VON CZYHLARZ.
3. Influenza as a Cause of Secondary Infection in the Exanthemata, with the Appearance of the Influenza Bacilli in the Blood. LUDWIG JEHL.

1.—Von Weismayr has examined 100 specimens of sputum from 81 phthisis patients. 35 of these gave tubercle bacilli alone; 20 also showed the streptococcus pyogenes; 13 the staphylococcus pyogenes aureus and albus; 10 gave both streptococci and staphylococci; and 3 cases revealed micrococci and diplococci also. The case-histories are given in full, with a table containing the result in the 81 cases. Of the 46 cases of mixed infection, staphylococci and streptococci were generally present. With mixed infection there is much fever, and the prognosis is less favorable than in pure phthisis. Besides mixed infection favors the destruction of the tuberculous tissue and hastens the formation of cavities. Von Weismayr concludes that mixed infection must be suspected in many cases of phthisis; cases. Of the 46 cases of mixed infection, staphylococci and prognosis is unfavorable; and that mixed infection may cause laryngeal complications. Finally von Weismayr hopes that more statistics upon the subject will soon be collected by other observers. [M. O.]

2.—Von Czyhlarz, after a review of the literature of the subject, describes a series of 18 experiments made upon guinea-pigs poisoned with strychnin, both in the air and in oxygen. Then followed 16 more experiments upon rabbits. From all of these, it was plain that oxygen weakened the intensity of the convulsions due to strychnin. From four experiments upon pigeons, von Czyhlarz shows that asphyxia, besides strychnin, hastens death, when a dose of strychnin had been given which alone would not have caused death. In 11 guinea-pigs the leg was ligated, strychnin injected, and 8 hours later, the leg was cut off, and the strychnin recovered. In 8 others, morphin was used instead of strychnin. From this it was seen that more than half of the poison injected could not be recovered. From 27 other experiments upon guinea-pigs, von Czyhlarz shows that, after the blood has been excluded from the leg to be ligated and injected, by an Esmarch bandage, the effect of the strychnin injected is much weakened. From 5 more experiments upon guinea-pigs, it was shown that long continued increasing small doses caused no preparation for receiving a large dose of strychnin. Death occurred immediately after the large dose. Four hens were then given increasing doses of strychnin, their excreta collected and examined for strychnin. The hens were then killed and examined for strychnin. The greater part of the strychnin given had disappeared, being found neither in the excreta nor in the dead hens. Dogs fed upon these hens showed no symptoms of poisoning. One hen, killed two weeks after the strychnin had been stopped, showed absolutely no strychnin in her body after death. [M. O.]

3.—Experiments have failed to isolate definite bacteria in many of the exanthemata. A long streptococcus has been found in some cases. Jechle has examined the expectoration and the blood in 48 cases of scarlet fever; in 23 cases of measles; in 9 cases of varicella; in 24 cases of pertussis; in 15 cases of diphtheria; and in 20 different affections in adults in which abundant influenza bacilli were found in the sputum. Of the 48 cases of scarlet fever, influenza bacilli were found in the sputum in 19, in the blood in 22; of the 23 measles cases, in the sputum in 18, in the blood in 13; of the 9 varicella cases, in the sputum in all, in the blood in 5; of the 24 pertussis cases, in the sputum in all, in the blood twice; of the 15 cases of diph-

themia, in the sputum in all and in the blood of one case. With the mixed infection the mortality was highest. Jehle concludes that in childhood, influenza is frequently found as a secondary infection. It is generally localized in the lungs, but may also be found in the tonsils. The influenza bacilli reach the blood in the exanthemata very rapidly, appearing in scarlet fever even before the eruption. In the other infectious diseases of children and in influenza of adults, the influenza bacilli are very rarely found in the blood. When the influenza bacilli are found in the blood, severe organic changes have occurred. Jehle believes that the exanthemata exert some predisposition to the entrance of a secondary infection into the blood. [M. O.]

REVUE DE MEDECINE.

April 10, 1901. (21me. Année, No. 4).

1. Lacunar Disintegration of the Brain and Other Cerebral Cavities. PIERRE MARIE.
2. Re-education in the Movements of the Heart, by Methodic Exercise. FERNAND LAGRANGE.
3. Angina and Stomatitis Due to Bacilli and Spirilli. NICLOT and MAROTTE.
4. Malaria and Mosquitoes. C. VANEY.

1.—Marie, who has made a large number of autopsies upon old hemiplegics, found but few areas of hemorrhage or softening, the great majority of brains showing **lacunar disintegration**. This consists of irregular cavities varying in size from a millet seed to a pea, the brain substance showing torn edges. In number they vary from one to ten, and they appear in both hemispheres. They are generally found in the lenticular nucleus and optic thalamus, but may also occur in the internal capsule, caudate nucleus, corpus callosum, etc. They are very rare in the cerebellum. With this lacunar disintegration the dura is adherent, the pia thickened, the convolutions and nuclei are atrophied, and the ventricles dilated. The choroid plexus may be cystic and the corpus callosum thin. Senility may be the predisposing cause, but arteriosclerosis is the main factor in the production of lacunar disintegration. Out of 50 brains of old men with this disintegration, cerebral hemorrhage was found in 16, and softening in 7. These lesions Marie believes follow lacunar disintegration. In all cases hemiplegia existed, 32 having had strokes of apoplexy, 13 of them more than twice. Marie also mentions three other cavities found in the brains of old men, the "sieve-like brain," well described by Durand-Fardel, frequently seen about the island of Reil, due to a general retraction of the cerebral parenchyma; **isolated perivascular dilatations** about a lenticulostriate vessel at its entrance to the lenticular nucleus, which may be as large as a bean, and is rarely seen; and **cerebral porosis** or cystic degeneration of the brain, a postmortem change, consisting of many cavities which may reach the size of a nut, found all over the brain. [M. O.]

2.—Lagrange believes that the human heart should be educated by **methodic exercise**, so that its movements will continue to be regular while the individual accomplishes a certain amount of work. Especially is this necessary where troubles of co-ordination exist in the muscles regulating the circulation of the blood. Effort, however, is too violent, and should be prohibited. When compensation fails the heart must be re-educated. This will be due to mechanical or functional causes. For either sort, massage and active movements of the extremities will do good. There should be no violent motion, no gymnastics. For the functional disorders all exercise must be rhythmic. Organic lesions will need regulated massage of the extremities for arterial hypertension; for arterial hypotension, deep massage of the abdomen, etc. It is by exercise that Lagrange believes **coordination in the movements of the heart** may be re-established. M. O.

3.—Niclot and Marotte describe 16 cases of ulcerative angina and stomatitis due to fusiform bacilli and spirilli. They give a complete review of the bibliography of the subject. It seems common among students and in the army. It cannot yet be proved epidemic. Symptoms are few, the chancreiform ulcers lying upon the tonsils, the mucous membrane of the gums, lips, or cheeks, with enlarged lymphatic glands, a fetid odor to the breath, and increased salivation. Appendicitis may occur as a complication, as do pulmonary or articular symptoms. Its course and duration are variable, the disease lasting from a week

or two, to two months. The only danger rests in grave complications. Erythema, purpura, etc., may appear. Tincture of iodine applications and a hydrogen peroxide wash form the only treatment. The diagnosis is settled by finding the fusiform bacilli and spirilli. It often resembles syphilitic or diphtheric angina. It is difficult to cultivate these bacilli or spirilli of Vincent, and inoculations often prove a failure. Niclot and Marotte made two series of over 75 experiments, with rather unsatisfactory results. No pure culture of either were obtained. Out of 32 inoculations, the two bacteria were found 14 times, the bacilli alone 7 times, the results being negative in 11 cases. Histories of the 16 reported cases follow in detail. They conclude that streptococci also exist with these bacilli and spirilli in inoculations, especially upon the mucous membranes. [M. O.]

4.—Vanev reviews the subject of malaria from the discovery of the hematozoa of Laveran in 1880, to the present time. He details the life history of the malarial organism, and mentions the **mosquito theory** advanced in 1884 by Manson. He describes the anopheles, and reviews the entire recent literature upon the subject. [M. O.]

JOURNAL DES PRATICIENS.

May 4, 1901. (XVme. Année, No. 18.)

1. A Case of Acute Cerebro-spinal Meningitis. DEBOVE.
2. The Spinal Method of Cocain Analgesia. TUFFIER.
3. Intestinal Pseudo-lithiasis of Medicamentous Origin. MAURICE DE LANGENHAGEN.

1.—Professor Debove reports a case of **acute cerebro-spinal meningitis** in a man of 25. He became ill suddenly, after having worked on an intensely cold morning, with pain in the forehead, back and neck, vomiting, and general malaise. The headache persisted, with fever and torticollis. The pain, with Kernig's sign, confirmed the diagnosis. Delirium, herpes, constipation, slight pupillary inequality, and occasional diplopia appeared. **Tâche cérébrale** was also present. Lumbar puncture gave a pure culture of the meningococcus of Weichselbaum, with many polynuclear leukocytes. Croupous pneumonia developed on the sixteenth day, and he died upon the 24th day. Lumbar puncture had been made twice, and baths of 95° F. were given four times daily. The autopsy showed widespread purulent cerebro-spinal meningitis. Debove believes that meningitis may be caused by the pneumococcus, the meningococcus, or the streptococcus. All three can be found in the nasal mucous membrane. He reviews the technique of lumbar puncture. [M. O.]

2.—After noting that Corning was the discoverer of the spinal method of cocain anesthesia, and that Bier operated by this method, but with faulty technique, Tuffier describes the precautions which he takes in carrying out the new method of spinal analgesia. The puncture must not be made in the operating room. The needle must be tiny, the cocain a 2% solution of cocain hydrochlorate. The patient should sit up, and the puncture should then be made on the level of the crests of the ilium. The injection should be made very slowly, taking a minute for injecting a gram of the liquid. The most common disadvantages of this method are vomiting during operation and headache after operation. During operation the mortality has been nil. Six cases, out of 2000 operations, died after lumbar puncture, three of them with tuberculous meningitis. [M. O.]

3.—Langenhagen reports the case of a woman aged 48, with **intestinal calculi** which she has been passing for a year. She had kept over 300 such stones. They were round, regular, grayish yellow, and calcareous in character. During this time she took four grains of sodium bicarbonate, calcined magnesia, and prepared chalk, in "cachets" at each meal. Upon stopping the medicine, no more calculi appeared. Chemical examination showed them to be formed of carbonate of lime and carbonate of magnesium, about half and half. As the medicine had been taken in "cachets," they may have formed calculi at once. Or when they reached the water in the stomach, a cement was probably formed immediately. But that this occur, it was necessary that there be no hydrochloric acid present. This was, then, much diminished, or absent. The literature of the subject has been cited in full. [M. O.]

Original Articles.

ATYPICAL AND UNUSUAL VARIETIES OF APPENDICITIS.*

By JOHN B. DEEVER, M. D.,

of Philadelphia.

Surgeon in Chief, German Hospital, Philadelphia, Pa.

Mr. President and Gentlemen:—

I acknowledge with much pleasure the honor of addressing this body, and hope that I shall be able to give you a few ideas that you can carry away that will be of practical value.

While I was as yet undecided as to what specific part of the vast domain of surgery upon which to speak to you, the subject which I have chosen was suggested to me by your secretary. I at once decided that nothing could be more appropriate or more likely to be of practical benefit. There is no disease which is trifled with more in the attempt to cure it with medicines and which causes as many deaths as neglected appendicitis.

Although appendicitis is in the majority of cases easy of diagnosis, if this condition be constantly kept in mind, yet there are many manifestations of this protean disease that are puzzling even to those with the largest experience with this affection.

The symptoms present in an attack of appendicitis depend upon a variety of factors, any or all of which may be involved in the case. These elements may be considered as: 1st, Anatomical; 2nd, Pathological; 3rd, The duration of the attack, and 4th, The idiosyncrasies of the individual. It is difficult to define a typical or usual form of appendicitis, for it is a disease which is prone to a great variety of pathologic phases. We can, I think, accept as the type of the disease that form in which the appendix occupies a position in the right iliac fossa, pointing toward or extending over the brim of the pelvis and overlying the psoas muscle. In this variety, we most frequently find the symptoms corresponding to the classical description and indicating the pathologic processes going on within the abdominal cavity. This definition falls short of accuracy from the fact that not infrequently, in cases in which the appendix occupies the pelvis, the pain in the early stages of the attack is referred to the left side of the abdomen. Nevertheless, I think that this variety can be accepted as the usual type of the disease; therefore this paper will take up the consideration of types of appendicitis in which the appendix varies from the above position and in which the pathological phenomena vary with the position of the appendix.

When the appendix occupies a position behind the cecum, pointing north or toward the liver or kidney we meet with a variety of the disease which is associated with many unusual phases and where a differential diagnosis is of vast importance and the difficulties manifold. One fact must be always kept in mind in a study of these cases, and that is, that if the inflamed appendix or an appendiceal ab-

scess is in contact with or contiguous to the kidney, liver or gall-bladder, there may be present symptoms which might lead to a belief that the primary disease is there located instead of in the appendix. It is therefore of prime importance to exclude disease of these organs by the proper examinations which in the case of the kidney would be the urine, and in the liver or gall-bladder the symptoms which characterize their diseases.

Let us now take up seriatim the diseases of the kidney which may be mistaken for an attack of appendicitis which has occurred post cecal.

Movable Kidney.—To arrive at a correct diagnosis between a movable kidney and a post cecal appendicitis, the following points must be duly weighed. Movable kidney is most commonly met with in nervous women who have gastro-intestinal disturbances. The attacks of pain are associated with nausea, vomiting, fever and *chills*. The urinary functions are disturbed as evidenced by frequent urination, which is apt to be painful and the urine is large in amount. The urine may contain blood and even pus; excess of uric acid or oxalates are of common occurrence. From the history of the case can be learned the frequency of the attacks of pain, the nature of the pain and the part of the abdomen to which it is referred and whether it is fixed or migratory; whether or not it occurred after the ingestion of a heavy meal, after exposure to cold, or to fatigue, or after unusual movement, or from position or indirect violence. The tenderness of a movable kidney is out of proportion to the degree of muscular rigidity and extends over a larger area than in a case of appendicitis. The above symptoms with the physical signs of a movable kidney make a plain case.

In the case of appendicitis, the three cardinal symptoms are: pain at first general or referred to the ensiform cartilage or around the navel, the latter becoming localized to the region of the appendix; tenderness, most marked in the immediate neighborhood of the appendix; and, rigidity of the lower portion of the right rectus muscle or the flat muscles of the abdomen overlying the appendix.

Floating kidney with twisted ureter may present symptoms very similar to an attack of post cecal appendicitis. The pain, however, radiates in the line of the ureter and is not increased by pressure to any marked degree. This condition, combined with a history of a movable tumor corresponding to the site of the kidney, the presence of blood in the urine, and changes in the amount of urine, and the absence of the cardinal symptoms of appendicitis will clear up the diagnosis.

Renal Colic.—Error in diagnosis between renal colic and appendicitis can only occur in the early stages of the disease. There are some cases where the pain of appendicitis is referred to the groin and is associated with retraction of the testicle and vesicle tenesmus. Renal colic, however, is usually ushered in by a distinct rigor, followed by excruciating pain in the loin posteriorly, usually increased by pressure. The pain radiates along the ureter and is somewhat relieved by voiding urine. There is no marked rigidity of the abdominal wall, and usually not marked tenderness in the right iliac fossa and the urine shows characteristic changes.

*Address on Surgery before the Wisconsin State Medical Society, Waukesha, June 27, 1901.

The X-ray is of use in making a differential diagnosis: A collection of pus behind the cecum may be mistaken for a surgical kidney, although it is not common for such a diagnostic point to come up. The pus resulting from appendicitis occurring post cecal is so rapidly destructive in its effects that it is unlikely to become chronic, while pyonephrosis is slow in onset and development. The local tenderness of pyonephrosis is always elicited by pressure in the loin, while that of appendicitis is located in the right iliac fossa as well. In pyonephrosis we have the characteristic findings in the urine of pus and blood; urine usually diminished in amount. Pain referred along the ureter and retraction of the testicle and irritability of the bladder. Usually in pyonephrosis a history of retroinfection from the bladder can be elicited.

A pyonephrosis in a movable kidney and especially in the absence of urinary symptoms presents a knotty problem. Here we must depend upon the tender, movable tumor and sick stomach without a tendency to let up, and the absence of the three cardinal symptoms of appendicitis.

Perinephritic abscess, and post cecal or post colic appendiceal abscess may be confounded, and, as a matter of fact, a peri-nephritic abscess may be appendiceal in origin. Personally, I believe that the majority of so-called perinephritic abscess cases are cases of post colic appendicitis abscess. The character of their onset will be sufficient to establish a diagnosis.

The following case taken from my list (Deaver's *Appendicitis*, Vol. I, 2nd Edition, p. 211), will illustrate the difficulty of the differential diagnosis:

The original diagnosis was appendicitis, and, on account of the desperate condition of the patient, when I saw him, an incision was made in the loin for the evacuation of an evident collection of pus. Recovery with repair of the wound followed. The patient, however, was unable to resume his occupation on account of localized pain, referred to and above the posterior half of the crest of the ilium. Six weeks after recovering from the operation for the evacuation of the abscess he was again referred to me. Upon examination the incision was found intact, but tender. Upon palpation over the appendix pain and resistance were noted. Removal of the appendix was recommended. When the patient was under the anesthetic and was placed upon the operating table, a distinct fecal odor, which was thought to be due to a bowel movement, was noticed. Upon removal of the antiseptic dressing which covered the proposed field of operation, it was found that the cicatrix had broken down and that fecal matter was escaping from it. Believing this to be a fecal fistula, the result of an original attack of appendicitis, I opened the abdomen, isolated the field of operation by gauze packing and located the appendix. The tip of the organ was perforated, and its lumen was found to be in direct communication with the fecal fistula. The appendix was removed and the wound disposed of after the manner of such cases.

Pyelitis and ureteritis can be mistaken for appendicitis. The differential points are the history of the infection by route of the ureter and bladder, the presence of tenderness at the bladder extremity of the ureter, as made out by vaginal or rectal examination, deep seated tenderness in the line of the ureter and the pelvis of the kidney, the absence of pronounced muscular rigidity; associated tuberculous or calculous disease of the kidney, and the presence in the urine of blood, pus, ureteral epithelium and gonococci.

I have operated on a case (*Treatise on Appendici-*

tis, Deaver's II. Edition, page 206), in which the symptoms were those of pyelitis and where the urine contained blood, pus and ureteral epithelium, but where the initial symptoms were those of appendicitis. The condition found was that of an appendix, which was adherent at its tip to the pelvis of the right ureter, and had ruptured at this point and the contents of the appendiceal abscess were being drained by the route of the ureter and bladder.

A differential diagnosis between an acute appendicitis and acute affections of the gall-bladder is at times one of the most difficult ones to make in the domain of intra-abdominal diseases.

Fulminating appendicitis and acute phlegmonous cholecystitis and gangrene of the gall-bladder or fulminating cholecystitis are diseases so similar in onset, symptoms, and results that they may present an almost identical picture and in certain cases are coexistent. But there are differences in the aspects of the two affections which serve to draw a line and enable us to establish a diagnosis, although the indications for early and prompt interference are so absolutely imperative that it is justifiable to proceed with an operation even before a positive differentiation is established. The following points are to be borne in mind—Vomiting occurs in both, but is less persistent in appendicitis; pain is intense in both conditions and is persistent, but in cholecystitis it is under the lower border of the ribs and radiates toward the right scapula while in appendicitis it is at first periumbilical and becoming localized, in a short time, in the right iliac fossa. In cholecystitis the pulse is quick and of small volume, the temperature high, the breathing shallow and rapid, and great depression, amounting almost to shock. Jaundice is not always present and its absence should not mislead one. Tenderness is present in both conditions, but it must be recollected that in appendicitis the point of greatest tenderness is usually located at a spot along the outer border of the right rectus muscle, where it bisects a line drawn from the anterior superior spine of the ileum to the umbilicus. In acute phlegmonous cholecystitis, on the other hand, and in gall bladder inflammations in general, the point of greatest tenderness is most frequently at the junction of the upper two-thirds with the lower one-third of a line drawn from the end of the ninth rib to the umbilicus.

In the less acute forms of inflammation of the appendix and gall-bladder and ducts, the diagnosis of each is difficult at times, but does not offer the obstacles that do the intensely acute forms just described.

Biliary colic can be mistaken for an attack of acute appendicitis. In both the onset is sudden and is accompanied with vomiting and colicky pain. In biliary colic the vomiting is more persistent, and there is apt to be a chill as an initial symptom. Tenderness is more marked in appendicitis. In biliary colic there is usually a history of previous attacks and jaundice is present oftener in this affection than in appendicitis, which, along with the characteristic color and pruritus and hemorrhagic tendencies, may persist during the interval between attacks. The location and degree of pain in the two affections differ, in that

the pain of biliary colic is more continued and more severe and radiates usually from the lower right chest margin to the umbilicus. In the latter stages of biliary colic the pain may become constant and involve the entire epigastric region or extend even lower; it will, nevertheless, usually, at intervals of two or three days, become localized and more acute in the region of the gall-bladder.

In appendicitis the localization is always toward, if not directly in the right iliac fossa, while between the severe paroxysms there is marked tenderness at this point and characteristic rigidity of the overlying abdominal walls. If, in addition to the above signs, there is found, as is frequently the case, gall stones in the stools, the diagnosis is positive. *Empyema* of the gall-bladder is a condition which may simulate appendiceal abscess. In the early stages of empyema of the gall-bladder the diagnosis can be made by the following points: the history, the onset, the location and character of the pain, the area and degree of muscular rigidity, and the character and position of the tenderness. A most important point in the differentiation of the two affections, if the patient be seen before adhesive inflammation occurs, is the movement of the distended gall-bladder with the movements of the diaphragm, and the rounded fluctuating swelling extending below the margin of the ribs.

Jaundice, as in the other affections of the gall-bladder, is rather unreliable as it is frequently absent. When it is present we know that there is an associated trouble in the common or hepatic ducts due to inflammation or blocking by stone.

The differentiation between a ruptured empyema of the gall-bladder and a ruptured appendiceal abscess is extremely difficult and at times is impossible short of operation. Points to be noted in the previous history and the fact that it is the upper portion of the right rectus muscle that becomes rigid in cases of ruptured gall-bladder will aid in the differentiation.

In hepatic and perihepatic abscess a differentiation can usually be made by the history, the location of the collection, the hectic temperature and emaciation and the absence of the characteristic history of an attack of appendicitis.

With all the points which we have at our command in making a differential diagnosis between acute appendicitis and acute disease of the kidneys, liver and bile apparatus, it is, nevertheless, not uncommon to meet with cases which are extremely puzzling and where a ripe experience comes in to carry us to a correct estimation of the pathological changes taking place in the abdominal cavity and help us to bring our patient to a safe haven of health.

There is another acute abdominal affection which may be confounded with appendicitis when the appendix holds a retro-cecal and retro-colic position, i. e., acute hemorrhagic pancreatitis. But this is so rare a disease that we need not to mention it. This much can be said, however, that it occurs in middle-aged, obese alcoholics, and usually follows debauch.

In the female, an appendiceal attack, and particularly when attended with suppuration, and where the appendix points toward or into the pel-

vis, may simulate any of the acute conditions of the uterine adnexa.

I have opened the abdomen for appendicitis and have found an ovarian cyst with twisted pedicle, hematoma of the broad ligament, extra uterine pregnancy, ruptured pyosalpinx, ovarian abscess, etc., but those were the days of early experience. The difficulties of a differential diagnosis in these various diseases is real and not fancied and often call for our greatest skill and acumen. It can be said for our comfort, that the treatment of all these diseases is essentially operative, a procedure which can be carried to a successful issue through the incision made for the purpose of removing the appendix.

In right-sided salpingitis, pyosalpinx, ovarian and tubalovarian abscess, the essential points of differentiation are the history of gonorrheal or septic infection by route of the uterus, the absence usually of vomiting, the lesser degree and location of the tenderness, the slower onset, and the location of the mass and the tendency to excessive flow at the menstrual period. Yet I do not consider an operation for pelvic disease finished without an investigation of the condition of the appendix.

In extra uterine pregnancy we have the history of one or more months of partial or complete suppression of menstruation, generally associated with signs of pregnancy and collapse supervening upon an attack of acute abdominal pain. These points, with absence of inflammatory symptoms, the latter being present, however, in late cases, and the finding of decidual shreds in the vaginal discharge will help to clear up a diagnosis. The pain is long continued and paroxysmal, but not like that of intestinal or appendiceal colic.

The following case will illustrate the difficulties which sometimes arise in making a diagnosis between acute pelvic and appendiceal disease:

J. G., aet. 26. History of an attack of acute abdominal disease occurring at the age of 12 years. She was sick for 7 weeks and recovered after the discharge of a large quantity of pus per rectum. The mass was confined to the right iliac fossa.

The present attack occurred at the end of a menstrual period and was brought on by violent dancing. She experienced a sharp pain in the right lower part of the abdomen, which grew steadily worse. There was rigidity, tenderness and vomiting present. A tender mass could be plainly felt in the vault of the vagina. She was operated on 20 hours later. The appendix showed chronic inflammation and was involved in a mass of old and dense adhesion along with the right tube and ovary. There was a large hematoma of the right broad ligament, which was evacuated through the vagina. The patient did well for 10 days, excepting the tendency of the vaginal opening to close. At this time she developed an acute intestinal obstruction for which her abdomen was re-opened. The patient made a good recovery and went home. One year after the original operation she was again operated to relieve adhesion between the ovaries and tubes, because of metrorrhagia and menorrhagia and dysmenorrhea.

This case will serve to point out to you the remote possibilities of appendiceal inflammation. It is not an uncommon occurrence to have an acute intestinal obstruction following operation for the relief of acute suppurative appendicitis, and especially so in those cases in which adhesions are numerous and dense.

An ovarian cyst with a twisted pedicle may pre-

sent symptoms resembling appendicitis. The onset of the symptoms of a cyst with twisted pedicle is sudden, and is usually caused by sudden changes of position of the body or to excessive peristalsis. If the twisting be complete enough to shut off the circulation, gangrene of the walls rapidly supervenes and the patient becomes rapidly septic. At first the peritonitis is local, but soon becomes general. Here we have some points of resemblance to appendicitis with abscess formation. The points of differentiation are the slow growth of the tumor preceding the acute condition; the shape and elasticity of the tumor, the difference in character of the pain and tenderness, and the widespread rigidity of the abdominal muscles.

I might go on to a discussion of some other forms of acute abdominal disease with which appendicitis can be confounded, but I fear I have taken up enough of your valuable time and will content myself by mentioning some of those which are met with. There are, splenic abscess, tuberculous peritonitis, circumscribed peritonitis due to inflammation of the right spermatic cord, psoas abscess, lumbar abscess, abscess of the abdominal wall, aneurysm of the iliac artery, enlarged mesenteric glands, and acute inflammation of the glands of the mesentery of the terminal portion of the ileum, mesenteric hematocoele, lead poisoning, incipient inguinal hernia. It seems inconceivable that acute appendicitis could be mistaken for hip disease or dislocation of the hip, but this error has occurred in a case I operated several years ago. The patient had a fall, striking his hip. He had some pain and tenderness in the hip joint. The day following he ate a large quantity of ice cream and acute abdominal pain soon followed. His physicians diagnosed dislocation of the hip and sent him to the hospital for reduction. The abdomen was generally distended, tender and rigid. The rigidity and tenderness, however, was more pronounced, immediately above the crest of the right ilium, just behind the anterior superior spine. Attempts to move the thigh caused excruciating agony. By examination I felt convinced that his condition was not due to his accident, but a post cecal appendiceal abscess. The belly was opened and a gangrenous terminal appendicitis with the appendix holding a retro-cecal position, lying upon the psoas muscle and surrounded by a small collection of offensive pus, was found. Inflammation of an exceptionally long appendix stretched along the ascending colon to or beyond the hepatic flexure gives rise to very confusing symptoms.

I have seen cases of subhepatic abscess consequent upon an appendicitis, which had been diagnosed empyema. In one, the abscess had pushed up the liver and diaphragm, giving all the signs of effusion in the lower right chest, which, added to edema of the chest wall, made the case very confusing. In the other, the abscess ruptured into a bronchus with expectoration of the pus, which made the diagnosis still more difficult.

Yet even in these cases the coexistent abdominal symptoms, previous history, mode of onset and absence of the usual causes of empyema made the diagnosis possible. In another of such cases the

abscess was situated nearer the median line and very closely simulated subphrenic abscess.

I have seen abscess due to appendicitis break through the posterior peritoneum and following the psoas muscle out of the pelvis infiltrate the tissues of the thigh as far as the knee.

Among the most difficult cases of appendicitis to diagnose are those chronic cases in which there are practically no symptoms except those of intestinal indigestion and dyspepsia. In all such cases it is well to palpate the appendix most carefully, and if it is found to be enlarged or tender remove it.

I have seen many such cases cured by this operation, done after years of suffering and invalidism from so-called intestinal indigestion. There are some cases of follicular appendicitis that simulate typhoid fever very closely in the early stages. In these cases a study of the blood is one of the valuable means of differentiation.

Appendicitis quite frequently complicates typhoid fever and should always be watched for. I have operated for appendicitis during the course of typhoid fever with the most fortunate results. Ulceration of Peyer's glands in the terminal portion of the ileum in typhoid fever with deposit of inflammatory exudate around or contiguous to the bowel, presents some points in common with appendicitis, therefore careful examination is necessary to determine between the two conditions in order that operation, if considered, be properly advised. I have seen a few cases of appendicitis with the appendix adherent to the bladder complicated with gonorrhea. Such cases present great difficulty of diagnosis, and the true nature of the trouble can only be ascertained by the most careful study, if, indeed, it is possible at all.

At the time of operation there is an atypical condition met with so frequently that it is worthy of note. In cases of acute appendicitis, with the appendix in the right iliac fossa, I have often found a collection of pus in the pelvis; therefore, I make it a routine practice to pass a drainage tube into the pelvis to determine this point and find pus in a surprisingly large percentage of cases.

After all, gentlemen, it is on the three cardinal symptoms of appendicitis, mentioned above, upon which we must rely most to make our diagnosis—pain, tenderness and rigidity.

The pain is a great stumbling block to many who do not remember that the initial pain may be referred to any part of the abdomen, and it only becomes localized to the right iliac fossa at the latter period. It is generally cramp-like and to a certain extent paroxysmal.

The tenderness is variable in degree, but a very valuable sign. It is in the great majority of cases most exquisite in a small area directly over the base of the appendix. In cases of referred pain a very valuable sign is the fact that pressure over the point of greatest pain gives pain not so much there as at McBurney's point. The rigidity is also as valuable, if not more valuable, than the other signs. It is best elicited by the gentlest possible pressure and is nearly always greatest over the appendix.

In conclusion, let me say that the greater my experience in appendicitis the firmer rooted become

my convictions in favor of early operation as being the only justifiable method of treatment.

The first attack, and the early hours of the attack, when the pathological lesions are confined entirely to the appendix, is the only time when the diagnosis is easiest, and is also the best time for operation, before complications have set in which not only make the diagnosis more difficult, but also the operation, as well, and render more certain the saving of useful lives which otherwise would be sacrificed to this variety of the dread monster, disease.

APPENDICITIS WITH THROMBOSIS AND SUPPURATION IN THE RIGHT ILIAC AND FEMORAL VEINS.

By JOHN GLENDON SHELTON, M. D.,

of Telluride, Colorado.

Surgeon in chief to the Montrose Hospital; Consulting Surgeon to the Telluride Hospital, Colorado.

Present illness. A robust laborer, 31 years old, was suddenly seized with a sharp pain in the abdomen. Shortly afterwards he felt chilly and weak, perspired some, and went to bed. During the next 10 hours the pain remained the same, and the patient vomited three times. He rested some during the next 8 hours. When he awoke the pain was not so severe, and was located in the right lower region of the abdomen. Patient said he had a fever, that he could not eat, and that his bowels would not move. He took some pills and succeeded in having a slight evacuation of the bowels on the fourth day of his illness. 8 or 9 days after the onset of the attack a sudden sharp pain occurred in the right leg. This was followed by blueness and swelling of the entire right lower extremity. These symptoms continued during the remainder of his sickness. The pain, however, was described as "a throbbing pain" during the last 12 or 14 days. The patient remained in bed, complaining of pain, fever and chilly sensations for five weeks, when the following examination was made: The patient, a well developed man, was very anemic and emaciated; anxious expression of face and eyes; very weak; cold perspiration on forehead and hands; tongue coated. Examination of chest and lungs was negative, except for the presence of many coarse moist rales over the lower lobes posteriorly. Heart not enlarged or displaced; no thrills. There was a faint systolic murmur heard all over the chest, but it was most marked over the pulmonary area. The abdomen was distended, tympanitic and motionless. No peristalsis heard on auscultation. Slight movable dullness in the flanks (?). The right thigh and leg were discolored, swollen, and pitted on pressure. No fluctuations could be found and no gangrene present. The extremities were cold, but the right was not of a perceptibly lower temperature than was the left. Nothing of importance was noted in the remainder of the examination. Examination of the liver and spleen was negative, and no rose spots were found. The pulse, extremely weak, but regular, was beating 152 times per minute, and the thermometer registered no abnormal temperature. The patient was considered to be in a dying condition and operation was not advised, but strychnine and salt solution were ordered. Four hours later the patient regurgitated some dark brown material into his mouth, and died one hour afterwards. Inquiries were made concerning the occurrence of previous attacks, but the patient's friends stated that they had never known him to be sick before.

Autopsy. The post mortem examination was made 10 hours after death by Dr. H. C. Hall, to whom I am indebted for the following report. The external examination has been previously stated. The peritoneum was everywhere covered with a whitish easily removable exudate. A slight amount of seropurulent fluid was found free in the peritoneal cavity. In the right iliac region the omentum, small intestine, cecum and ascending colon were matted together and firmly adherent to the posterior abdominal wall. In separating the adhesions many collections of foul smelling pus were found. The appendix was gangrenous and almost completely separated from the cecum. No solid particles (as enteroliths) were found within, or near the appendix. The retroperitoneal glands were enlarged, but not softened. The right common iliac, external iliac and

femoral veins were enlarged and of a semi solid consistence. On opening them many collections of pus were found, the largest in Scarpa's triangle, and the next largest at the point of bifurcation of the common iliac vein. The internal iliac vein was not examined. Adhesions were found about the iliac and femoral arteries, but these vessels did not seem enlarged or solid, and no openings were made into them. **Pericardium:** The pericardial cavity contained a slight amount of straw colored fluid. Both parietal and visceral layers were perfectly smooth. **Heart:** Seemed slightly enlarged (not weighed). The semilunar valves were not subjected to the water test. No abnormal changes were found in any of the cardiac valves. The mitral orifice admitted 3 finger tips, the tricuspid admitted 5 with difficulty. The beginnings of the coronary arteries were normal. The endocardium was smooth; the linings of the aorta, pulmonary artery and coronaries showed no areas of thickening. The heart muscle seemed pale; was slightly flabby; and, on the cut surface, had a slightly granular appearance. No increase of connective tissue was observed. The liver, kidneys and spleen were slightly enlarged, and presented a granular surface on sections. No gross changes were present. The lungs were normal except for an excess of dark fluid in the lower lobes posteriorly, the presence of muco-purulent material in some of the bronchi, and a small irregular cicatrix in the right apex. The bronchial glands were not examined. Examination of the small and large intestines showed nothing abnormal. The nervous system was not examined. No note was made of changes in the stomach, pancreas, adrenals, bladder, prostate, testicles or thyroid.

There are three questions of importance concerning thrombosis of the iliac veins in appendicitis. First, how frequently does it occur? Second, what causes it? Third, how can it be prevented? I have seen 186 cases of appendicitis, and the one reported, in this paper, is the only case in which the iliac veins were involved. Mynter (*Appendicitis*, p. 91), states that phlebitis and thrombosis of the iliac vein may occasionally be found. In his report of 75 cases he records two cases (Nos. 9 and 13) as being complicated with iliac thrombosis. Case No. 9 was operated upon on the 5th day after the attack. The next night she collapsed suddenly, "and died with symptoms of an embolus, probably from the iliac vein." No autopsy was made, and no symptoms referable to involvement of the iliac vein were complained of. In case No. 13 of Mynter's series, the patient complained of pain in the right thigh followed by swelling of the foot and leg, elevation of temperature and pulse rate, and tenderness and hardness along the right femoral vein. These symptoms occurred on the 9th day after the attack, and the swelling and tenderness in the region of the vein did not appear until the 14th day, or 5 days after the pain in the thigh was complained of, and 9 days after operation had been done. Willy Meyer (*Annals of Surgery*, May, 1901) reports two cases of iliac thrombosis following operations for appendicitis. In case No. 1 the pain and elevation of pulse and temperature came on the first day after operation; the swelling and edema appearing two days later. He was unable to feel an induration along the course of the vein at this time. A few days later the entire extremity became edematous and an infiltrated cord corresponding to the course of the femoral vein was present. These symptoms lasted about three weeks and then the opposite side became similarly affected and presented similar symptoms extending over a period of four weeks. Recovery in this case was complete.

In Meyer's second case the patient complained of pain referred to the area corresponding to the

passage of the left femoral vein under Poupart's ligament. The symptoms in this case corresponded to those in case No. 1, the difference being that in case 2 the symptoms came on at the beginning of the 2nd week following operation. The symptoms were milder and the opposite extremity became affected 10 days after the involvement of the first one. I have been unable to obtain records of cases of iliac and femoral thrombosis occurring in cases of appendicitis treated in the institutions in which I now work, and I could find no record of such complications occurring in the cases of appendicitis treated in Cook County Hospital, Chicago.

The second question that I have to consider is, what causes the thrombosis? The cause in the case which I report, was doubtless involvement of the vein from direct extension of the inflammatory process. Among causes other than infection are: (1) Contraction of inflamed retroperitoneal tissue around the iliac vein. (Hawkins.) (2) Compression of the veins by bandages, or by constipation. These were suggested by Lennander as possibilities only. Contraction of the retroperitoneal tissue could not be considered a sufficient cause of thrombosis in cases in which the complication occurs early in the primary attack, as it did in the case herein reported, but it seems reasonable to suppose that the contraction might act, at least, as a predisposing cause in chronic cases. In discussing this subject, Osler says: "In the healing of extensive inflammation about the margin of the pelvis the iliac veins may be greatly compressed and one of my patients had for months edema of the right leg, which is now permanently enlarged." I have nothing to offer to prevent thrombosis occurring in these cases. Early operation, of course, is desirable. Lennander recommends that the foot of the bed be elevated in cases in which a thrombosis of the iliac or femoral veins might occur. I have not resorted to his method in any case with the idea of preventing thrombosis.

GASTRO-INTESTINAL AUTOINTOXICATION OCCURRING WITH FORMS OF MUCOUS COLITIS IN CHILDREN.*

By HENRY KOPLIK, M. D.,
of New York.

Former President of the American Pediatric Society.

In the strictest sense of the term, gastro-intestinal autointoxication takes place in conditions in which foreign toxic substances are produced in the stomach and gut as a result of abnormal fermentation. These toxic substances are absorbed and cause pathological manifestations. (Weintraub.) The products of normal digestion, when produced in increased quantities, may be absorbed and cause autointoxication. According to the French school, even in the normal condition the absorption of such substances (peptones) is constantly going on, but pathological manifestations are avoided by the splitting up and neutralization of these products in the wall of the gut and in the liver.

Symptomatically, gastro-intestinal autointoxication may manifest itself in the skin by changes of

color, such as anemia, bronzing or icterus. In the muscles we have polymyositis. On part of the intestinal canal there are nausea, vomiting, diarrhea, constipation and pain. The functions of the kidney are interfered with, as shown by the appearance of albuminuria, hematuria and biliary pigment in the urine, acetonuria and diaceturia. The nervous symptoms which are a part of the symptom-complex of gastro-intestinal autointoxication consist principally of vertigo, headache, delirium and even stupor and coma. Finally there are disturbances of the functions of the heart and lungs, with loss of the general nutrition.

The cases which I shall describe in this paper form a class by themselves. They occur in children from the fourth to the later years of child life. The children have as infants been either breast or bottle-fed. They have always suffered from some disturbance of the functions of the gut. As a rule, these children have from infancy been constipated, or this condition has been a very trying problem at various periods. In some cases the parents suffer similar intestinal disturbances. Certain articles of diet, such as unboiled milk or varieties of vegetables, have disagreed with them. There are times when these children physically are not as strong as they should be for their age; they are anemic, slow in their movements, peevish, suspicious; again they are bright, have a good color, and are vivacious. These intervals of improvement and depression have dominated their lives. The one prominent symptom is the constipation. On close examination there is nothing in the physical state either of the heart, lungs or kidneys to account for attacks which seem to be species of intestinal toxemia. These children, after living for months on a carefully selected diet, in which certain articles known to be irritating have been excluded, in a moment of indiscretion, may partake of some simple, but hitherto avoided, article of food. They then after 24 hours will develop symptoms of such alarming nature as to arouse even in the mind of the physician a solicitude as to their ultimate recovery; in other words, these attacks are of a distinctly toxic character. In all of the cases which I shall describe and which belong to the same category, there have been at one time or another, alternating with the constipation, discharges of mucus, either in small or large masses, from the gut. There has been in all of the cases which I refer to a mucous colitis. The exact nature of this mucous colitis, first described in children by Eustace Smith, is still very obscure. It is for this reason that we should analyze them in the light of our more modern knowledge of the toxemias and diseases of the gut.

The case with which I desire to illustrate my theme, and which is similar to two others, is the child of healthy parents. He is now six years of age. He has had very slight signs of rickets; was bottle-fed. When 18 months old he had an attack of acute gastro-enteritis, which became a subacute enteric catarrh. The boy recovered. Following this attack he remained pale, and in the following winter developed an endocarditis after a possible influenza. He made a good recovery, but always remained pale, slow in action, and inordinately constipated. The movements in this child of two years of age, in spite of mixed diet with cream and the administration of cathartics, such as cascara, were passed in the form of scybala. The urine examined at the time of the endocardial attack contained a slight trace of albumin, so slight as to be

*Read before the New York Academy of Medicine, May 16, 1910.

scarcely recognizable. In the summer of his fifth year the boy developed, without any apparent cause, having been under a very rigid diet, an attack which I shall describe later on. He recovered from this attack, and in the following winter, having all along suffered from constipation, developed another attack, and still a third, of a very alarming nature.

The child for some days prior to an attack is noticed to be very pale and listless. There are dark rings under the eyes. The appetite is capricious. There is vertigo, even when the child lies in bed; he will say that articles of furniture move about him. The patient wakes up in the morning, complains of a feeling of nausea and pain in the epigastrium, asks for water, and begins to vomit. The vomited matter at first consists of some food which was partaken of the previous day. Then, after this has been rejected, the vomiting persists, glairy mucus is brought up and the vomiting occurs even in the recumbent position. Everything, even albumen water, is rejected. It is noticed that there is very little absorption and the fluids are vomiting in much the same quantity as introduced. There is no diarrhea, and a cathartic may have been administered and followed by a very good result. In spite of this, the vomiting continues for one or two days at intervals. During this time there is a full-bounding high-tension pulse from 128 to 148 per minute. The heart impulse is forcible, and in one case the radial arteries could be felt as high as the mid-region of the forearm. In all cases albumin is present in the urine to a greater or less extent. At the outset in one case the albumin in the urine gave a very marked reaction with abundant hyaline casts of small calibre. In the other cases there was simply a trace of albumin in the urine. In one case the urea excreted in a boy of five years amounted to 13 grammes, then rose to 15 grammes, and finally to 19 grammes in the 24 hours. The urine in one case was of a specific gravity of 1020, acid, and contained abundant urate of ammonium crystals when passed. There is in these cases abdominal pain. In some the pain is not a prominent symptom; it is a feeling of distress in the region of the umbilicus. In other cases the pain is quite severe, and in one patient simulated the pain found in appendicitis. There is, however, no distension of the abdomen. Examination may reveal a distended cecum, but no distinct pain on pressure. The pain seems to be in the gut and is not intensified on pressure. The nervous symptoms in all of these cases give great concern. The patients seem very much prostrated; they are pale, and the face is anxious. They seem to be suffering from some noxious poison. The temperature is scarcely half a degree above the normal, or it may at first be a degree or a degree and a half above the normal and rapidly reach the normal. The odor of the breath is of interest in these cases, in view of the case published by Senator, in which the expired air had a distinct odor of H₂S. In one of my cases, a marked mucous colitis, during the toxic attack the breath had the same odor as the flatus expelled. The boy passed quantities of this gas by the anus quite unconsciously. The father of the child, a physician, called my attention to this fact. In another case the breath had a so-called indescribable sweetish odor. In the third case the breath was offensive and the tongue coated.

After the symptoms have subsided and the bowel has been emptied, such patients, after two or three days pass either large mucous casts or masses or small amounts of mucus with the movements. These masses of mucus are sometimes very ill-smelling, and may be passed for days or weeks after such attacks, and finally the movements may become normal both in form and consistency. The mucus or shreds of mucus may disappear entirely for weeks or months from the feces. In one case in which large masses of mucus were passed, I examined these masses and found them principally composed of mucus, round granular cells from the surface of the gut with bacteria. There is nothing like a membrane. It was rather gelatinous. In the intervals the children regain their strength and color; the albumin disappears from the urine; the casts can no longer be found, and the patients seem to have made a complete recovery. The constipation alone remains. There is no pain whatever; no colic. I cannot describe these attacks better than by referring to them as crisis. They remind one very strongly of a toxemia. They are no doubt brought about by the constipated condition of the individual and the stasis of feces in the gut. The mucous discharges seem to be the accumulations in the gut of what, under normal conditions, would be discharged in inappreciable quantities with the daily evacuations; instead of this, the mucus seems to accumulate until an attack is impending. The whole picture reminds one, with the bounding pulse, forcible heart and vomiting, of what is seen in uremia; and yet there is no edema of the tissues, and the urine in the intervals of these attacks is perfectly normal. The diminished urea, the evident excess of ammonium in the form of ammonium urate in the urine, point to some form of intestinal toxemia similar to what is seen in cases of chronic intestinal infection and toxemia of chronic marasmus and atrophy. In these cases Czerny and his pupils have shown that there is an increased elimination of ammonium through the urine and feces pointing to a marked disturbance of metabolism and the normal processes in the gut. Ammonia is increased in any form of gastro-intestinal disturbance. Under normal conditions the ammonia is excreted in the form of urea. If there is an excess of acids produced in the gut, the capacity to neutralize these acids with alkali is diminished, the acids combine with alkalies drawn from the tissues and appear in the urine and excreta in the form of increased ammonia in combination. Thus Keller has shown that this form of toxemia is really an acid intoxication. This acid intoxication is favored by fat and nitrogenous food and diminished by a vegetable diet. This is the form of intoxication which I think we have in the cases of intestinal disease just described.

Treatment.—The immediate attack can be successfully treated in all these cases by absolute rest in bed. All food by the mouth is stopped. In the beginning of the attack large warm enemata (110°) of the Cantani salt solution are given twice daily. After the bowel is completely washed out, the patient is given a nutritive enema of a solution of somatoze, made by dissolving one teaspoonful of somatoze in eight ounces of cold water. Two ounces of this solution is given to the patient every two

hours. The vomiting and pain, if the latter be present, is relieved by small doses of codeia. Strychnia is given later in the case, after the first 24 hours of the onset of symptoms. The recumbent position is maintained until the patient is quite strong and the heart has returned to its normal action. If the patient has recovered, the treatment of the interval is one of the most difficult problems in the management of these cases. We try to regulate the diet, if possible, by first placing these patients on a skim-milk diet. I find that cream (fat) is especially noxious in some cases. The children will not take it; fat causes alarming symptoms, such as nausea. These patients get along by a carefully selected mixed diet. Skim-milk, cocoa, cereals of all kinds, meat once a day, and vegetables which leave very little residue seems to be the best form of diet. We study the movements and avoid those vegetables which appear undigested in the feces. Spinach is of such a character that it is not assimilable in these children. Strained purée of peas and baked potatoes seem to be the most easily assimilated. Fruit juices, such as orange juice, are well borne.

The constipation is most difficult to eliminate. One patient does very well with a small dose of strychnia once a day and an enema twice weekly; another must be given hydrochloric acid after meals with the above; another does well if given cathartics daily, such as cascara. If an attack is impending (and in these patients we can forestall one by watching for symptoms of intoxication, such as pallor, listlessness, peevishness and loss of appetite with coated tongue), a good dose of Carlsbad salts seems to be a safe and effectual cathartic, on account of its alkalinity and thorough action. I have not succeeded in completely curing the main condition at fault in these cases, but I have tried to outline to you my efforts in this direction.

TREATMENT OF INFANTILE DIARRHEA.

By WILLIAM H. ROBEY, JR., M. D.,

of Boston.

Physician to Out-Patients at the Boston City Hospital and for the Diseases of Children at the Boston Dispensary; Assistant in Bacteriology, Harvard University.

Of one hundred and seventy-two cases of diarrhea seen in the Children's Room of the Boston Dispensary, one hundred and sixty were diagnosed as fermental, eight as mechanical, and four as ilio-colitis. The ages ranged from three weeks to three years. Only twelve of the mothers stated that their children were fed absolutely on the breast as the majority which were called breast-fed, admitted on questioning that other food was allowed from time to time. In the cases of mechanical diarrhea there was either a history of fruit seeds or skins being ingested or they were washed out in the enema.

In the ilio-colitis cases there were blood and mucus in the stools with some bits of membrane. The movements were usually frequent and small.

The average temperature taken in the rectum was one hundred; a temperature as high as one hundred and four was rare. The temperatures were not uniformly as high as those of some previous reports, and while it has been suggested that the lower temperature may possibly be due to the late

stage of the disease when first under observation, a further inspection of the records has not been conclusive. Like the character of the stools, the temperature may change within a few hours and is not a reliable guide to the condition of the patient. In the only case of cholera infantum which I saw last summer, the temperature was a hundred and one and a half 5 or 6 hours before death, although the nervous symptoms were evident at the time.

If we knew the specific cause of infantile diarrhea we might or we might not be assisted in our immediate treatment of the case; there is no doubt that the knowledge would be of great value in prophylaxis. At present no special organism has been found to account for fermental diarrhea, although several observers have isolated what they considered the specific cause. We do, however, appreciate its contagiousness. As to the action of the various organisms, we believe that the condition is first a local one due to the toxic products of enormously increased numbers of bacteria and that later these products are absorbed, causing the constitutional symptoms.

The treatment is obviously:

- a. To cleanse the bowel of the bacteria and their toxic products.
- b. To give the remaining bacteria as unfavorable conditions as possible for further production.
- c. To soothe the irritated intestine where the continuance of the condition makes this necessary.
- d. To support the patient against constitutional symptoms, as fever, nervous irritability, etc., as in other acute diseases of childhood.
- e. To guard against infection of others by isolation when possible and by carefully washing the hands after handling the stools in order not to infect other food and common household articles.

Naturally, the small intestine must be cleansed by a purge, and for this purpose calomel 1 gr. was given in 1-10 gr. doses at $\frac{1}{2}$ -hour intervals. It has been asked why castor oil was not given since it has such soothing properties. In treating infantile diarrhea, especially in dispensary practice, one must try to accomplish as much as possible at the first visit for obvious reasons. The gastro-intestinal tract of the infant being in an irritable state, the oil is more apt to be vomited; whereas, I have never known this result with calomel; in fact, it will allay vomiting should that dangerous symptom be present. Furthermore, castor oil is such a common household remedy that it may have been tried already, while calomel in divided doses keeps the mother busy and aids her patience in carrying out the second important step in the treatment: starvation.

Each case of diarrhea before leaving the hospital had the bowel washed out by a trained nurse. This was done by passing a large soft rubber catheter into the bowel allowing the tepid normal salt solution to flow in during the passage, thus dilating the bowel and facilitating the introduction. At least two quarts of the salt solution were allowed to run in, the bag of the fountain syringe being held about three feet above the table.

The character of the washings from each case was noted and a record made of the reaction, odor, color, presence of curds, fat globules, mucus, blood,

and membrane. The color and odor may, however, alter in a few hours. The washing was repeated upon as many successive days as the case required; being out-patients, it could not be done oftener—twice daily I think sufficient. Personally, I cannot see the objection to washing out the bowel in every case. Kerley thinks that it is unnecessary in a bowel that is constantly emptying itself, but in our experience it has seemed to allay the fever and the nervous irritability of the child. No special attention was given to anatomical position in administering the enema. The majority were given on the back. The results in any position were equally good. It has been considered objectionable by some because most children are frightened by the operation and will cry and struggle; but I have only seen one child that was appreciably exhausted by it and that was a feeble infant already much debilitated by a long continued diarrhea. They are not more frightened than by the ordinary examination of the throat or taking of the temperature, and the majority of them quiet down after the tube has once been introduced and become used to subsequent washings, as to other manipulations of the physician or nurse. Irrigation is the most rational treatment when there is any question of irritation from foreign bodies, such as fruit skins and seeds. An Italian infant, fifteen months old, of fine physique and always well, was brought to the dispensary because of frequent convulsions since the night before. When seen the convulsions occurred on the average of two every five minutes. The mother stated that she had no idea of the cause of the sudden illness. We washed out in the enema quantities of water-melon seeds, string-bean pods and tomato skins, and during the hour that the child remained in after the washing, but one convulsion occurred.

The simple outfit needed for irrigating the bowel may be readily carried by the physician to any case.

As important as cleansing the bowel of the toxic products is not to give the gastro-intestinal tract more work to do nor the remaining bacteria any more culture media upon which to grow and thus continue the production of toxins. Hence food was withheld for 24 hours and albumin water (whites of two eggs added to a pint of boiled water with a pinch of salt and a teaspoonful of brandy) was given—a half teacupful every two hours. Sterile water could be given just as well, but in dispensary practice especially the mother is more ready to carry out this very important part of the treatment if she is giving what she considers to be a food.

It is a good plan to tell mothers going into the country with their children to stop food for 24 hours at the very onset of a diarrhea. If there is vomiting the stomach must be washed out as well as the bowel, and this can be done with the same kind of catheter. If the temperature is high and the nervous symptoms marked, a tepid bath will be a valuable addition to the treatment. This was employed in some of the cases before they left the dispensary, but in the majority of our cases the temperature not being high, the desired effect was produced by the enema.

After 24 hours the majority of cases require no further medication and depend for continued improvement upon the gradual resumption of food.

All cases were put upon a weak modification of sterilized milk, the point being to have the percentages low enough. We have not found it necessary to use dextrinized barley or other starch foods, the very dilute alkaline milk mixtures being sufficient.

As was shown at the outset, breastfed babies seldom have diarrhea, and when they do are easily returned to the breast after 24 hours starvation; especially if the interval between feedings is increased. Where there was still some irritability of the bowel, the sub-nitrate of bismuth was given in at least 20 gr. doses every three hours. Where bismuth was given immediately without the initial purge, the results were unsatisfactory, and in almost every case where it was tried the treatment had to begin over again upon the following day. Opium was used only where pain was a marked symptom, and then only where the stools were frequent since the danger of opium in stopping peristalsis and thus favoring absorption from the bowel is very well known. The necessity of cleanliness, pure food and fresh air was carefully explained to each mother.

In a small number of our cases which showed no improvement after three days, we referred them to that excellent charity, the Boston Floating Hospital, where the required treatment could be carried out under proper atmospheric conditions.

SPASTIC ILEUS.*

By EDWARD QUINTARD, M. D.,
of New York.

(Continued from Page 111).

Haidenhain's Case. (12) A 30 year old healthy fisherman up to time of hospital entry entirely well. On February 17th he was taken with vertigo, nausea, violent vomiting and complete stoppage of stool and wind. Pain in the abdomen was not present. On the 22nd, with his temperature normal, and pulse 64, he continued to have nausea, violent vomiting and complete stoppage of stool and wind but the physical examination of the abdomen was negative. In spite of energetic measures, such as high enemata, etc., the symptoms kept up. No opium was given. On the 22nd of February, i. e., 9 days after the first symptoms began he was operated upon. The exploration resulted negatively. The small intestine was found to be completely empty and collapsed, or, contracted. In one place a round worm was readily palpable through the intestinal wall. It was motionless. There was no obstruction of any kind to be found. The abdominal wall was closed with a feeling that an unnecessary and dangerous operation had been performed. Strangely enough the vomiting now ceased, but the intestinal occlusion kept up. It was not until 3½ days after the operation that stool occurred spontaneously. Morphine had been given but no opium. There was no temperature and recovery was complete.

Quintard. "My own two cases of spastic ileus are as follows: My first case was that of a young society woman aet. 25, who came from a markedly neurotic family, and whom every now and again during the course of several years, I had treated for slight and transient nervous disorders, and for a mild form of anemia which showed itself from time to time. She never had shown any of the true symptoms of hysteria, but the digestive disturbances which in her case occasionally showed themselves, were undoubtedly due to disorders of the abdominal sympathetic system. Two years previous to the attack about to be described, the patient had married. Her married life brought many cares and anxieties, especially as her husband experienced about this time serious business reverses, and her worry over money matters was very great. The strain told on her nervous system and gradually but surely she drifted into neurasthenia. One evening, after a hearty meal, at which among other things she had partaken of green corn, fruit

*Read before the American Gastro-Enterological Society, Washington, D. C., May 1, 1901.

and pickles, she was seized suddenly with a violent abdominal pain which was so severe that it made her feel faint. I was sent for at once and found the patient already in bed with hot water bags applied to her abdomen and groaning with pain, the worst of which seemed to be located on the right side of the abdomen, and, for the most part, above the umbilicus, but which at the same time was more or less general. The abdomen, on examination, was found, so far as could be seen, perfectly normal, no distention, no tumor visible or to be felt on palpation; no tenderness on pressure. The patient now vomited a good portion of the undigested food and at the same time felt an inclination to pass stool, but neither stool, nor yet flatus could be expelled. The patient in this case suffered intensely and the pain grew worse in paroxysms although there was a constant pain in the region mentioned. The pain finally became so great that morphine was given and the hot water bags were changed to hot stupes, these latter relieving the patient more than anything else. Dr. A. A. Smith was called in consultation, and after the most careful examination possible could find no definite cause of the trouble. We came to the conclusion at that time that it was a case of spastic ileus, and this proved to be correct, for although the patient continued in more or less pain for four days, during which the same symptoms continued, and during which despite cathartics and enemata complete suppression of stool and flatus continued, together with vomiting of bile stained fluid, nevertheless, at the end of that time and quite suddenly, the patient expelled considerable amount of gas which was presently followed by stool of a semi-fluid character, the attack ending almost as abruptly as it had commenced. The temperature during the entire attack was practically normal but the pulse varied a good deal, and became quite weak and rapid during and after a paroxysm of pain, so much so in fact that we used strychnine hypodermically.

Since the first attack I have treated the patient for a similar one, and once when away for the summer, she had another, lasting several days.

My second case was that of a merchant, X. W., aet. 36, a highly intelligent, but nervous man. He came to me in March, 1900, to consult me for what he called peculiar attacks of stomach trouble. This history is as follows: Was well up to 1892. Then after a hard year of business, came down with neurasthenia and acute attack of catarrhal gastritis. From that time up to the year of the first attack, which was 1897, he was in fairly good health, only at times very nervous. He drank moderately, but was an inveterate smoker, smoking as many as twelve cigars daily and inhaling constantly. During the fall of 1897 he had again many business cares and anxieties, and on the day before Thanksgiving he felt particularly tired and nervous, and, in order to brace up his appetite, indulged in cocktails, and at dinner ate some roast duck and drank some ale. After this he experienced a good deal of abdominal distress, which the patient said was not cramp-like at all, but was a "steady, peculiar pain about the navel." Tried to move bowels that night, but without success. The next morning, still feeling the distress and pain he walked to the doctor. The pain was so severe that he had to walk "doubled up." He was given a dose of *Ol. Ricini*, but it did not work. He took another and with equally useless result. The pain was now so severe that he rolled about in bed and even bit the bed clothes, so great was his distress and agony. The patient neither passed flatus nor stool. Patient now began to vomit, at first bile; then, according to himself and family, fecal material, i. e., a fluid of fecal odor. Morphine was given, and this seemed to allay the vomiting and distress somewhat, yet he for several days more was in great pain, and did not pass either stool or wind, but vomiting still continued. At the end of this period he experienced a sudden desire to stool and against the orders of the doctor and the nurse, he walked to the bath-room, and there expelled per rectum a great amount of gas. After this enemata given worked. The next attack was in July, 1898, when he again had an attack such as described above. From that time on several such attacks, but not so long or severe. As the nurse, who had taken his temperature in the attack of 1897 could not be found, and as the physician himself, who attended the man, no longer remembered the pulse and temperature, my notes in these respects are deficient. This must be added, however, that the patient during such attacks did not turn yellow,

and that the most careful search for gall-stones resulted negatively. When the patient first came to me on March 2nd, 1900, his condition was as follows: His general condition was that of a man suffering from a mild degree of neurasthenia with quite a decided secondary anemia. His blood examination showed red cells, 3,929,000; white, 5700. The red cells were fairly regular, somewhat pale, and there were a few polkilocytes. Small lymphocytes, 28%. Large lymphocytes=10%. Polymorphonuclear neutrophils=61%. Eosinophils=1%. Hemoglobin=78%. The urine was negative, except for the ratio between urea and uric acid, which stood 36. The ratio of mineral and etheral sulphates was normal. Physical examination gave absolutely negative results.

Test breakfast=normal. He was treated for his anemia and his general nervous condition. Was placed on a liberal diet, and his cigars and alcohol were cut off. Everything went along well until April 19th, 1900. On that day the patient went to his club for dinner. Although feeling somewhat tired he sat down to a hearty meal, consisting of meat, vegetables and some new Bermuda potatoes, he was hungry and he ate very fast. After leaving the club house, he had scarcely walked the distance of a block, when he was suddenly seized with a violent pain in his abdomen, which was so very severe that he hailed a cab and was driven home. When I arrived, I found the patient in bed, with cold feet and hands, and an anxious and somewhat drawn face. His pulse was 90, of fairly good force, but somewhat wiry. His temperature was normal. He complained of great pain in the abdomen, but could not localize it. The abdomen was slightly distended, but there were no painful points on pressure. The patient had tried to have a stool, but found he could not, nor could he pass any gas, he had, however, vomited a quantity of undigested food. At four o'clock on the morning of the 20th, his temperature was 100.4-5; pulse 90. This is the highest the temperature or pulse ever went. At 8 A. M. his temperature was 100.2-5; pulse 80. He complained of a throbbing pain all over his abdomen and of pressure in the epigastrium; expelled some gas by mouth. At noon he was given a high oil and hot water enema: result, negative; it did not even return. Hot stupes were applied to the abdomen, which afforded some relief to the distress, and at times agony of the patient. Morphine 1-8 hypodermically was given at about 2 o'clock. Shortly afterwards he vomited a large quantity of undigested food, large pieces of the Bermuda potatoes and pieces of meat, which had evidently been swallowed whole, being readily seen in the vomit. At 3 P. M.—pulse 78; temp. 99. A saline enema was given and retained—neither stool, nor yet gas, passed per rectum. Patient's abdomen by this time was somewhat distended and tympanitic, there were no visible peristaltic movements, he was vomiting undigested food and biliary matter; he was in great distress and I suspected ileus. I now called in Dr. Frank Hartley. Together we again made a most careful examination of the patient. From the previous history, from the character of the pulse, from the temperature, and from the fact that despite the great pain and distress there were no very serious or threatening symptoms, we continued with the morphine, washed out the stomach, gave calomel by the mouth, and continued the hot stupes from time to time, and the enemata. Not, however, until the evening of the 22nd, i. e., the third day from the commencement of the attack, did we obtain any encouraging results. Then a soap and hot water enema brought away a few fecal masses. A few hours after this another soap and hot water enema was given with a large semi-fluid yellow stool as a result, and the expulsion of a great amount of gas. From that time on the patient improved, and in twenty-four hours he was up and about, although somewhat weakened by the attack. Only once during the entire three days of his illness did his pulse go above 90, or his temperature reach higher than 100.4-5 and that was at four o'clock on the morning of the 20th. After that his pulse varied between 65-84; his temperature between 98.2-5-99. There was no fecal vomiting but the patient's stomach was washed out several times during the course of the attack. The Urinalysis on the afternoon of the 20th showed the following. Sp.gr. 1028. Albumin—trace. Sugar—negative. Bile—negative. Indican—considerable excess. Phosphate—some excess. Microscope—a few hyaline casts, few blood cells, few pus cells, few bladder epithelial cells, few uric acid crystals. There was no jaun-

dice throughout the attack and the examination of the feces gave negative results.

It seems to me that this again is a fairly typical case of "Spastic Ileus," seen in a neurasthenic man and that the cause of this particular attack was in all probability his rapidly eaten and undigested meal. After the attack the patient followed treatment very carefully for several months and it is now over a year and he has had no return of the attacks, so far as I know.

Etiology.—Aside from basilar meningitis in its first stages, as well as other diseases of the central nervous system, we have seen that Spastic Ileus after all is not such an uncommon ailment as many suppose. We see it most frequently in those who are suffering from neurasthenia or hysteria, as in the cases of Chérchevsky, Treves, Schloffer, and my own two cases.

The general disorder in these cases seems to render the abdominal nervous system peculiarly liable to disturbed innervation, and, as a consequence of this, any particular shock or irritation seems at times capable of producing "Spastic Ileus." S. Talma, in his highly interesting article, "*Zur Kenntnis des Leidens des Bauchsympathicus*," relates many very interesting cases of the manner in which the diseased sympathetic ganglia and plexuses affect the various abdominal organs, and, amongst others, the case of Spastic Ileus quoted. Again, we have seen "Spastic Ileus" arise reflexly, as in the cases of Tansini and of Grundzack, and possibly even so small an object as a round worm may be the cause of the irritation, as in Haidenhain's case. Again, it occurs in the course of systemic poisoning, as in Murphy's case of lead colic, or in the course of an organic spinal disease, as in Sandoz's case, where it seemed to be the first pronounced symptom of an ataxia, or, again, but what, as Nothnagel says, must be extremely rare, as a distinct neurosis. Once more, to rapidly review the etiology, we see Spastic Ileus occurring:

- (1) In the course of a neurasthenia or hysteria.
- (2) Reflexly, as is seen at times after operations, or when foreign bodies irritate the intestinal canal—the spasm in this case taking place not only at the point of irritation, but involving other portions of the tract as well.
- (3) From irritating substances and poisons in the intestinal canal, such as toxins, ptomaines, leuko-ptomaines, or when there is general tissue poisoning from such products.
- (4) From peritoneal irritation (not necessarily septic).
- (5) Diseases of the sympathetic ganglia.
- (6) As a distinct neurosis.

Diagnosis.—Of course, if there is a history of previous attacks, this is our greatest aid in diagnosis. But when it comes to the diagnosis of cases where there are no such histories, it is at times extremely difficult, if not quite impossible, to tell whether we have to deal with a case of Mechanical or a case of Spastic Ileus. As a rule, it may be said that although the subjective symptoms of Spastic Ileus are very severe, that, nevertheless, the general condition and appearance of the patient does not give one the idea of a profound systemic disturbance, that the temperature and the pulse in Spastic Ileus, as a rule, follows more nearly the normal, and that in the case of Spastic Ileus we do not get a visible

peristalsis. As to the latter point, however, we must not forget, as Boas very rightly says, that we frequently miss this last phenomenon in cases of mechanical ileus, and we all of us have seen visible peristalsis in cases where there was no mechanical obstruction. As to the temperature and pulse, in hysteria, this is at times so very misleading and under certain conditions causing Spastic Ileus might be so raised that here again we have no definite clue. The urinalysis in my own cases showed some excess in the indican, but then almost all cases of neurasthenia, and many cases of hysteria, at least in my experience, show a similar condition, and, as a consequence, such tests cannot be relied upon. The sound "household judgment of Laurence Sterne's" must, therefore, in these cases, be with us, and the general conditions of the patient should guide us much more than any particular symptom. My earnest advice to every practitioner of medicine is, however, that unless he himself be a surgeon, to, in every and all such cases, call in a surgeon at once. By so doing he may save himself many bitter reflections in the end, for the mistaking of a Spastic Ileus for a Mechanical Ileus by a surgeon would not be nearly so serious a matter since abdominal sepsis has been perfected, as would be the case of a medical man who should happen to mistake a mechanical for a Spastic Ileus. Finally, we must remember the lessons taught by such cases as described by Dr. Milkuliez and Dr. J. W. Bryant, where the patients are afflicted with that most loathsome of habits—coprophagy. Otherwise a serious abdominal operation may be performed without cause.

A word here as to the cause of the fecal vomiting seen in such cases. From Galen, of ancient times, who was the originator of the Theory of Antiperistalsis, to Hagnenot, who, in 1713, gave us what for a better name may be called the hydraulic pressure theory, the subject of the cause of fecal vomiting has been one of the most mooted of the centuries. To enter into the discussion ourselves would be foreign to the object of a clinical paper, but for such as desire to read a few of the ablest articles on the subject, they are referred to the various articles and monographs given at the end of this paper. A word as to the Hagnenot theory may, however, not be out of place.

Hagnenot's theory of fecal vomiting was published in 1713, although this same theory has been wrongly credited to Van Swieten. According to Hagnenot, fecal vomiting occurs as follows:—If at one particular spot the lumen of the intestine is completely stopped, there accumulates above the occlusion thin watery, or thin mushy intestinal contents in great quantities. At this point there results by reason of a simultaneous accumulation of gas a not inconsiderable pressure, which by every inspiration, by the movements of vomiting, and especially by energetic contraction of the intestinal musculature is yet further increased. Under the influence of this pressure the stagnating, readily movable, fluid contents of the intestines above the occlusion, gives way, and as its passage is stopped below, follows in the direction of least resistance, which is upwards, and, as a consequence, finally reaches those intestinal coils adjacent the stomach.

If these coils become filled with the decomposed intestinal masses, a regurgitation, or, rather, as Hénle strikingly defines it, an overflow, takes place into the stomach, the mucous membrane of the latter is irritated by the intestinal contents, and vomiting follows. (Fleisher.)

It would seem, therefore, that whereas in many cases of Mechanical Ileus, the Hagenot theory is sufficient to explain the occurrence of fecal vomiting, that in the vast majority of cases of Spastic Ileus it is not. For in cases of Spastic Ileus we find two distinct objections to the acceptance of the Hagenot theory, which are as follows: In the first place, if we accept the Hagenot theory, we must imagine a dilatation of the intestine above the point of obstruction, whereas we have seen that the very reverse of this was found in such cases as reported by Wölfer, Schloffer and others. For here the laparotomy revealed an intestine, the different portions of which were in spastic contraction, but above which contracted portions the gut was collapsed or normal. Secondly, in almost all cases of Mechanical Ileus, and in every case where the Hagenot theory is accepted, the stagnating, fecal matter vomited is fluid. And in reference to this we may mention that Schloffer, in his very able article, "Ueber Ileus bei Hysterie," suggests that in those cases where we find solid or formed fecal matter vomited, we have every right to suspect that the case is one of Spastic and not Mechanical Ileus, and that then the possibility of there being a hysterical basis for the attack must be considered, and again, to quote the last-named author more directly, "As to the question of how antiperistalsis occurs in cases of hysteria, we cannot answer, for we know so little of the nature of hysteria itself. But we do know, on the other hand, how manifold and variable and unreliable are the disturbances which hysteria can produce."

What is far more to the point, it seems to me, in these cases, is the fact that unless we accept the theory of antiperistalsis, we cannot explain the cases as reported by such keen and scientific observers as Briquet, Treves, Schloffer, or Rosenstein. In these cases the sick man for us as physicians ought to have far more weight than the well dog. Personally, therefore, I am of the opinion that at times antiperistalsis with fecal vomiting as a result does occur; or, to put it in other words, that there exists such a phenomenon as a pathological antiperistalsis.

Finally, as to the treatment: In all such patients as thorough and as complete a subjective and objective examination should be made as is possible. The blood, the urine, the gastric contents, the feces, should all be the subject of patient and diligent search. No subjective or objective symptom should be passed over hurriedly. We should remember that every symptom, no matter how trivial, has its own significance for the wise physician. When we have to deal with neurasthenia, or hysteria, hygienic conditions must be strictly carried out. And in many of these cases the only salvation is a rest cure. The proper and judicious use of hydro-therapeutic measures, in some cases the wet pack, in others the spray, in its many forms, electricity, general and local, massage,—being careful,

however, not to begin abdominal massage too early in such cases where there is hyperesthesia of the celiac or other ganglia or plexuses—passive and active movements, all these measures will, in properly selected cases, stand us in good stead. Nor should we ever forget that it is just as important for many of these patients that we build up their moral as well as their physical tone. So far as drugs are concerned, of course their selection will depend upon the various general and local conditions found. During acute attacks, and when once we feel sure that we have to deal with a Spastic and not a Mechanical Ileus, then the local application of hot moist stupes, together with carefully conducted intestinal lavage, and if vomiting is obstinate, or fecal vomiting supervenes, gastric lavage may bring about the desired result.

Purges and all gastro-intestinal irritants are to be avoided. Anti-spasmodics, such as extract of belladonna, atropine, or camphor, and the coal tar products seem at times to relieve the spasm much more quickly and efficiently than opium. We may here mention that S. Talma found antipyrine and quinine signally successful in many cases where the sympathetic ganglia and their plexuses were involved. My own experience with disease of the sympathetic ganglia also would lead me to the conclusion that the coal tar products and quinine give at times good results, but in neurotic people we frequently notice a peculiar idiosyncrasy as to coal tar products, especially in reference to their depressing effects, and we should therefore be careful and avoid too large doses of such remedies at the start.

Lastly, if in an acute attack of Spastic Ileus, all medical measures seem unavailing, and the patient's condition becomes more serious, laparotomy should be performed, but, of course, long before this, if a wise medical man, you will have had the sound advice of your consulting surgeon.

REPORT OF CASES EXAMINED FOR THE NATIONAL JEWISH HOSPITAL FOR CONSUMPTIVES, AT DENVER, COLORADO.

By SALING SIMON, A. B., M. D.,
of Denver, Colorado,
Admitting Physician to the Hospital.

It would probably not be out of place before giving the report of the cases examined for admission to the N. J. H. for Consumptives, during the past eighteen months, to explain how this most worthy institution is conducted, and how admission thereto is obtained.

The hospital is entirely under Jewish lay management, and is supported by the Jews throughout the U. S. It is, however, non-sectarian as to the religion of the patients admitted. The institution is under the control of a National Board of Directors, consisting of thirty five members, residing in the principal cities of this country. The immediate management is in the hands of a local board of managers, of whom there are eleven, assisted by a medical advisory board of three physicians. Among the rules governing the admission of patients, the following is quoted: "The National Jewish Hospital for Consumptives at Denver is intended for the treatment of tubercular diseases only, among the indigent, in whom the disease is not sufficiently advanced to preclude the possibility of recovery or the arrest of the disease within the time, assigned for the treatment." Every applicant desiring admission to the hospital must have the endorsement of the local director,

and be examined by a properly authorized physician of the city in which he lives, and the examination blank together with the application submitted to the Denver Board for action. Upon arrival in Denver, he is at once admitted to the hospital, and re-examined by the admitting physician. Should the answers of the applicant be untrue, or the examination found unsatisfactory, and in the opinion of the admitting physician, hospital treatment not likely to prove beneficial, the applicant is returned to the place from which he came. A guarantee that the patient, when discharged, will not become a charge on the city of Denver, signed by three responsible persons, must accompany each application. During the first six months of the hospital's existence, a number of advanced cases of tuberculosis were admitted. These patients had been in Denver for some time, and there being plenty of room at the hospital, admission was readily granted, consequently a great number of deaths occurred at the hospital during the first year. Since then only those in the early stages of pulmonary tuberculosis, who are likely, in the opinion of the admitting physician, to be improved by hospital treatment, have been admitted. Following upon the enforcement of this rule, the number of deaths has been materially decreased. During the first six months twelve patients died, during the second six months eight, and during the last five and a half months three, making a total of twenty-three deaths.

At the present time every applicant, who has resided in Denver for less than a year, is referred to his former home city for endorsements of his application, by the resident member of the National Board. A patient who comes to Denver for the purpose of obtaining admission to the hospital, to avoid having his application go through the regular channels, will find it a difficult matter to gain entrance. During the past eighteen months three hundred and fifty applications for admission were made; two hundred and twenty-eight patients were examined, and two hundred and four were admitted. One hundred and forty-six were rejected, either because they had relatives who could provide sufficient funds for their care, or because their condition was too far advanced, and for other reasons. Patients are admitted for a six months' term, which may be extended upon the recommendation of the medical advisory board, but no patient is permitted to remain longer than one year. Patients are examined every two months by the attending physicians to note their progress. Their sputa are examined upon admission and several times during their stay, and again upon discharge. Patients are weighed weekly to note gain or loss.

There were one hundred and seventy-four males and fifty-four females examined; one hundred and thirty were single, ninety-two married and six widowed. Thirty-one were between the ages of ten and twenty, one hundred and twelve between twenty and thirty, fifty-six between thirty and forty, twenty-five between forty and fifty, and three over fifty.

All cases have been divided into four stages: Those showing slight involvement of one or both apices, that is, some dulness, increased fremitus, and prolonged expiration, without rales, are classed as incipient. Those cases in which the physical signs

are somewhat more pronounced, and where rales are heard, are classed in first stage. Those cases in which there is marked consolidation, and beginning softening with numerous moist rales, are classed in the second stage; and those cases in which softening is marked, and cavities are in process of forming, or have formed, are classed in the third stage. Such a classification, it will be understood, is more or less arbitrary and often difficult to make, as there are no distinct dividing lines between the ending of one stage and the beginning of the next. Where the examiner was in doubt how to classify a case, he was assisted in coming to a decision by the patient's general aspect and the rational symptoms.

Of the two hundred and twenty-eight cases examined, twenty-five were found to be in the incipient stage, nine of whom had the apices of both lungs involved, fourteen the apex of the right lung and two the apex of the left. Twenty-four of the incipient cases were decidedly improved by hospital treatment, and one, a woman, died; she had slight tubercular infiltration of the larynx, and was also four months pregnant at the time of her admission. After her delivery of a seven and a half months' child, her lungs and larynx grew rapidly worse, and she died within four months of her accouchement.

Forty-two were in the first stage of tuberculosis, and of these five had the upper lobe of the right lung and apex of the left lung involved. Seven had the left lung and apex of the right, twelve had both lungs nearly equally, and seventeen had the upper lobe of the right lung alone, and one the upper lobe of the left lung alone involved. Of the first stage cases thirty-three were improved, eight remained stationary, and one died.

Eighty-two of those admitted were in the second stage, and twenty-six had the right lung more extensively involved than the left, nine the left more than the right, fourteen both lungs equally, and twenty-three the right lung alone, while ten the left lung alone. Of the second stage cases fifty-four were improved, seventeen were unimproved, eight became worse, and three died.

Forty-three of those admitted were in the third stage, the lungs in five being in a fibroid condition. Of these eight had the right lung more extensively involved than the left, sixteen the left more than the right, eight both lungs equally, six the right lung alone, and five the left lung alone. Of the third stage cases ten were improved, twelve unimproved, six worse, and fifteen died.

Of the twenty-four not admitted, eighteen were too far advanced, two were not tubercular, and in four the physical signs were too indefinite or slight. There were also four cases of miliary tuberculosis admitted, three of whom became worse and one died. Three cases of phthisis florida were admitted, of whom one became worse and two died. Two were admitted in whom the physical signs were indeterminate. Both were discharged improved. Two were admitted and afterwards found to be non-tubercular, and were discharged.

Summing up the totals, we find, that out of the two hundred and four cases admitted in the hospital, one hundred and twenty-five were improved, thirty-nine were unimproved, seventeen became worse, and twenty-three died.

One feature that invites attention is the predominance of the right lung involvement over that of the left; in the incipient cases the ratio was seven to one, in the first stage seventeen to one, in the second stage two and a half to one, and in the third stage cases six to five.

Many of the cases marked improved were practically well when discharged, but sufficient time had not elapsed, from the disappearance of all symptoms of the disease, to warrant one in pronouncing them well or cured. Nearly ninety per cent. of those discharged still live in Denver, and vicinity, and while not under direct observation, are frequently seen, and the majority of these report themselves continuing well and able to work. It is the intention of the hospital authorities to devise some means of keeping patients under observation after their discharge, in order that the statistics in the future may determine the number of permanent cures obtained. In recommending the discharge of patients from the hospital, the attending physicians are guided by the improvement that has taken place in the patients' general condition, such as gain in weight, healthy appearance, as well as the disappearance of all marked pathological signs in the lungs and tubercle bacilli from the sputum.

Colds contracted in exposure from their work was assigned as a direct cause by eighty-three patients. La Grippe was given as the cause by twenty-four. Six had slept with some member of the family who had tuberculosis. Forty-five gave various other causes, and the remainder assigned no definite cause.

The occupations of the patients were exceedingly varied, seventy-four different ones being given. Forty-five were employed as tailors or in allied work, twenty-eight were employed in stores as sales people or clerks, twenty-three in house-work, fourteen peddlers, eight cigar makers, six laborers, and six school-children. The largest number, it will be noted, were employed as tailors, most of them in the sweat shops of New York City and Chicago. This certainly justified the authorities in taking cognizance of this evil, as was done by the legislature of New York State and the health boards in enforcing certain hygienic and sanitary rules in the tenements, where these people live and work. The next highest number were employed as clerks or salespeople in stores, and would indicate that here, too, health boards might find a field for investigation and improvement. Nearly all those engaged in house-work were women, most of them as wives and at the same time assistants to their husbands in their work. The peddlers, a large proportion handling old clothes and rags, form the next most numerous class. If one were to deduce anything from these figures, it would be the influence of in-door work and bad hygiene as contributing to produce tuberculosis.

The family history in one hundred and fifty-two cases was negative. In two both parents had been affected with tuberculosis; in twenty-two either one parent or the other had been affected, and in eight one or more brothers or sisters had tuberculosis; in fifteen cases some paternal or maternal relative had been affected, in two cases wives of the patients had been affected, and in one the husband. I cannot help but noting here how small a part, if any, hered-

ity plays in causing tuberculosis. Many of the patients examined for the hospital, as well as those in private practice, express their surprise, that they should be affected with tuberculosis, since no member of the family had ever had it. Long years of the establishment of the belief that consumption is hereditary, has left a deep impress upon the minds of the laity, as well as the profession, which will require time to efface.

Among the important symptoms noted, hemorrhages were present in ninety-eight cases and spitting of blood on one or more occasions, in twenty-three patients. One hundred and seven had not coughed up any blood during the course of their illness. One hundred and twenty-one patients had night-sweats, in sixty-four of whom they ceased on coming to Colorado. Ninety-two had never had any. Seventy-five per cent. of the patients had fever, varying from one-half to four degrees; this occurred mostly in the afternoon. A rapid pulse even without fever seems to be almost the universal rule. The microscopic examinations of the sputa showed tubercle bacilli present in one hundred and sixty-six cases, and absent in thirty-three; there was no report of the remainder.

I shall briefly touch upon the treatment of the patients at the hospital. The climate, nutritious food, and personal hygiene, were mainly relied upon. Patients are encouraged to keep out of doors as much as possible, and to further this purpose, games are provided for their amusement, upon the porches and grounds surrounding the hospital. The food provided is the best the market affords, and is properly prepared. There are a number of special diets upon which the patients may be placed, as directed by the attending physicians, besides numerous extras, which may be ordered for the patients. It has been the aim of the staff to give particular attention to the quality and preparation of the food provided for the patients, and in this it has found the ready co-operation of the Board of Managers.

All patients are instructed in the danger that lies in communicating the disease through the sputa, and paper spit-boxes are provided for them, which they are required to carry with them in and around the hospital. They are not allowed to expectorate in or use handkerchiefs. Pieces of cheese-cloth, which can be cremated, are provided for their use. Various other measures to secure personal cleanliness are enforced. In regard to medication, no systematic attempt has as yet been made to use true specific medicines. Patients are treated symptomatically, and the majority of the attending physicians avoid the use of large numbers of drugs.

It has been found that the fever in this disease is best combated by putting the patient to bed. One patient was kept in bed almost constantly for four months before his afternoon rise of temperature ceased. In treating excessive cough heroin is the drug most frequently used.

I desire to acknowledge my indebtedness to Dr. John Elsner and other members of the staff for the use of their reports of the cases examined by them; to Dr. Philip Hillkowitz for the microscopic examinations of the sputa; to Dr. M. Collins, superintendent of the hospital, for other data required in making this report.

JOURNAL DE MEDECINE DE BORDEAUX.

1. The Dreamy Delirium of the Intoxications and Infections. E. REGIS.
2. Four Cases of Glioma of the Retina. LAGRANGE.

1.—With any toxo-infection some confusion and delirium occur. The delirium occurs during sleep and is of a peculiarly dreamy character. It may cease when the patient awakes, or be continued. But in the auto-intoxications and the infectious diseases, the delirium is stronger, there is true somnambulism. These patients talk and walk in the dream, and they often retain a fixed idea long afterward. The condition could be discovered and combated by hypnotism. It may also be noted after accidents, operations, etc. Somnolence is seen in gastro-intestinal or hepatic intoxication; catalepsy, tetany, or eclampsia with renal intoxication. It is easy to differentiate this dreamy delirium from that noticed in the insane. Yet the former may with time develop into the latter. [M. O.]

2.—Lagrange reports four cases of gliomata of the retina, with detailed histories. They occurred in young children, were all operated upon successfully, and have all recovered. The diagnosis was in every case confirmed by microscopical examination of the extirpated tumor. Three were true gliomata, one a neuro-epithelioma. [M. O.]

May 19, 1901. (31me. Année, No. 20).

1. Purulent Otitis Media. E. J. MOURE.
2. Recovery from Acute Mania following the Appearance of a Large Carbuncle. G. LALANNE.

1.—Acute suppurative otitis media in children may be mild or severe. The mild attack will go as quickly as it came, the pain disappearing and the discharge ceasing. This generally is seen with nasopharyngeal adenoids. In severe cases vomiting and meningitic symptoms appear, lasting several days. In adults there is greater pain, but fewer general symptoms. Pain over the mastoid is only found after suppuration has occurred. With influenza the discharge may be hemorrhagic. Hearing is always diminished. Before the ear-drum is perforated, it bulges. After 10 days of suppuration, the mastoid pain should disappear, and the secretion gradually cease. As prophylaxis, the adenoids should be removed. Counterirritation behind the ear may be begun at once. Antiseptic solutions should be used in the nose, throat, and ear. If the pain is severe, the ear drum must be perforated. Insufflation of air by Valsalva's or Politzer's method will do good. The injections of hot antiseptics into the ear should be continued until the discharge stops. An astringent powder may be insufflated into nostrils and ear also. As soon as symptoms of mastoiditis develop, the bone should be incised and the pus evacuated. [M. O.]

2.—Lalanne reports a case of acute mania in a man of 58. He had already had three such attacks, all due to the same cause, an argument with his neighbors about the limits of his property. This attack had lasted five months when a large carbuncle developed on the back of his neck. When this reached the stage of free suppuration, the mental symptoms gradually disappeared and he was cured in six weeks. Off and on through the literature, similar cases are reported. Some alienists have applied counterirritation to cause suppuration in the hope of curing mania. Lalanne suggests the formation of a fixation abscess as a means of curing mania. [M. O.]

A Case of Primary Tubercular Ulcer of the Skin of the Penis. M. A. Tshienoff (*Medicinskoie Obozrenie*, April, 1901.) describes a case in which a tubercular ulcer made its appearance on the prepuce and gradually extended to the glans. A piece of tissue removed for diagnostic purposes presented the characteristic appearance of tuberculosis of the skin and was found to contain tubercle bacilli. The patient, a man of 43, was otherwise perfectly healthy. An alcoholic and a man of very loose morals, he indulged in promiscuous intercourse, having had connection with prostitutes just prior to the appearance of the ulcer. While the author considers infection *per coitum* possible in this case he does not feel justified to make a positive assertion. He cites authorities to prove that genital infection is quite possible. [A. R.]

Immunity from Malaria.—In his book on Malaria (which we have reviewed in another column), Celli discusses the subject of immunity. His discourse on this subject is of great interest. He says that it is proven that among the lower animals there are immune races. Bovine malaria, for instance, rarely attacks the indigenous oxen of the Agro Romano, but it decimates imported cattle. Thus of 100 Dutch cows imported thither, all but one solitary cow perished in a severe epidemic of malaria. Celli believes that no human race is by nature immune from malaria. Negroes are no more immune than whites. In regions where severe malaria exists the negroes may acquire a relative immunity, but if other negroes, not thitherto exposed, are brought into such localities, these latter are decimated by the disease. Celli believes that a white population, whose ancestors have for centuries lived in intensely malarious regions, comes to acquire a relative immunity. He instances the population of the Pontine Marshes—one of the worst infected regions in Italy. This population has become resistant to malaria, but a colony of Venetians, brought thither, was literally decimated by the fever, and the survivors fled in terror. The indigenous population, it is true, sometimes suffers, but it continues to live in localities where other populations would soon be exterminated. The hut-dwellers of the Agro Romano, who are badly clothed, fed and housed, are descended from a population which for centuries has inhabited this infected region, and they suffer much less than strangers. Celli thinks that this immunity may be due in part to those acquired habits, especially in relation to habitation and work, which experience has taught the people through many generations. In this case it seems to us that it would not be a true immunity, but a form of prophylaxis. Celli, however, sees here the action of a Darwinian law; the part of the population which survives is that which is specifically more resistant. In other words, there is a survival of the fittest, and thus from generation to generation a process of natural selection acts, and, as Tommasi-Crudeli has shown, produces a race continuously more resistant to malaria. This is an interesting appeal to the all-pervading philosophy of evolution.

Some individuals, however, are absolutely immune for causes peculiar to themselves. Thus Celli cites the cases of four men at Sezze, in the Pontine Marshes, who are thus immune from malaria notwithstanding that they have lived exposed for years, without taking any precautions. They work hard, live on poor food, and sleep in the open air in the marshes, where they are continually exposed to the bites of mosquitoes. Yet these four persons were in good health, and without enlargement of the liver and spleen. Such immunity in persons who have never had the disease cannot be explained on the theory of an antitoxin. In fact, Celli tested this question, by taking serum from these individuals and injecting it into a man whom he afterwards inoculated with malarial blood. The result proved that there was no immunity secured in this man. Moreover, it is well known that an attack of malaria does not establish an immunity, for the infection easily recurs. Celli made numerous scientific tests of this whole subject. He recognizes that an acquired immunity is sometimes obtained, and gives instances in which individuals far advanced in malarial anemia and cachexia, have recovered and remained resistant. But such an immunity has not yet been produced artificially, except with a few drugs (but that is a different matter).

Acting on various theories, Celli bled patients during defervescence, in the hope of obtaining an antitoxin, but without success. The serum thus obtained was not effective either to prevent or to cure. He sought to obtain also a pyrogenic toxin, even by using the red blood corpuscles from a malarial patient, at the time of a paroxysm, but without success. He then turned to the lower animals; for instance, the oxen of the Agro Romano, which are known to be immune. He expressed the juice from the brain, lymphatic glands, spleen, bone-marrow, liver, and pancreas. But neither preventive nor curative power was observed. Finally he made an ingenious test of the mosquito itself. Reflecting that *Culex* does not transmit the plasmodium, he argued that this particular mosquito may contain some principle that is noxious to the germ. Therefore, he prepared a juice from many of these insects. But this, too, was without success. While these re-

sults are not encouraging, still Celli points out that there is a solid basis to start from in the fact that some individuals, and even whole populations, are absolutely or relatively immune. Perhaps this problem, which is of the greatest hygienic and economic importance, will yet be solved along the lines suggested by the eminent Italian investigator.

Professor Koch's Statement.—There have not been wanting occasions upon which Professor Koch has made some rather startling announcements in science which have subsequently not been sustained by ample knowledge or more extended research. His most enthusiastic supporters do not even now claim that he has discovered a new fact. The distinction between bovine and human tuberculosis had been made before him; for an American investigator, Dr. Theobald Smith, claimed some years ago that in his studies in Texas he had been led to believe that the bovine bacillus differs from that of man. It sometimes takes some years for a new idea in science to cross the Atlantic Ocean from west to east, and such a vagrant idea then turns up unexpectedly and with startling effect. But if Professor Koch has not discovered a new fact he has possibly helped to settle a controversy by finding out a new way of demonstrating a theory. On this point, we must wait and see. It is obviously easy enough to demonstrate that the human bacillus can be transmitted to the lower animals, but it is next to impossible to prove the converse. We have not yet come to the stage when we dare produce tuberculosis by experiment in man. Civilization is not prepared for this final step. It never will be. Therefore, the *experimentum crucis* is wanting; and mere clinical observations are somewhat untrustworthy. Hence those London hygienists who are answering Koch by pointing to children's hospitals in which the inmates die of tuberculosis because they are fed on tuberculous milk, are not furnishing conclusive proof. Something more direct is wanted than such statistics from the kitchen.

The question whether tuberculosis can be conveyed from animals to human beings has up to the present time, in the opinion of some persons, been an open one. There has been little or no demonstration for or against. We know that this statement will be disputed by some, but our reply is that we need positive, not merely presumptive, proof. Dr. Leonard Pearson, in another column of this number of the *Journal*, has presented the positive side of the argument with an authoritative pen. In favor of the theory that tuberculosis can be conveyed from animals to man is the converse, that this infection can be conveyed from man to animals. This raises a strong inference in favor of the thesis—but after all it is only an inference, a rea-

soning from analogy. On the other hand, the claim that cases of human infection with bovine tubercle are wanting, must be received with caution. Since meat and milk are so universally consumed, who will venture positively to deny that any of the thousands of cases of tuberculosis are thus contracted? Here again, real scientific proof, such as we have in the case of malaria, is wanting.

It is just possible that the public has been stampeded into an unnatural fear of milk and meat. Governments have possibly allowed themselves to be hurried into unwarrantable expenditures. But we should clearly recognize that one of the evil effects of Koch's pronouncement may be a relaxation in our sanitary methods, with consequent carelessness in our dairies and shambles. This would be deplorable. In conclusion, the discussion which is bound to rise and vibrate about Prof. Koch's theory, will make us take soundings and see just where we are.

The Crusade Against Bovine Tuberculosis Must Continue.—The mischief that may come from a misinterpretation of Koch's statement is obvious, but it is not one for which he is to be held entirely responsible. The flaring headlines in many of the daily papers announcing in effect that bovine tuberculosis is innocuous to man, were quite characteristic of newspaper enterprise, but they were evidently premature. The saner and less sensational of our newspapers discuss the subject intelligently and wisely in their editorial columns. There will be no excuse for any one—much less for any one in authority—to relax due care and vigilance. Dr. Samuel G. Dixon, of this city, calls attention to the fact that milk can be contaminated with tubercle bacilli after it has left the cow. The sources of such infection are in milkers and milkmen, who may be tuberculous, and thus contaminate the milk in its transit to the consumer. In this way milk can convey human tubercle bacilli.

The vital question after all is: How do the bacilli of tuberculosis gain entrance into the human body? Let us recall the fact that in many infectious diseases this is still *terra incognita*. How extraordinary, almost startling, was the exact truth on this subject in the case of malaria, and how contrary to all preconceived ideas. Have we the right to assert dogmatically that the bacilli are swallowed with our food? The practical indications so far are clear. The stamping out of tuberculosis in cattle should continue, but it should be clearly understood that this is for the purpose primarily of securing healthy herds, and that it is not an absolute guarantee of security for man. The proper methods of stamping out tuberculosis in the human family are by the establishment of special hospitals and sanatoria; the registration of every case; the

disinfection of rooms that have been occupied by consumptives; and the rigid care of the sputum. One of the last acts of the recent Congress in London was to pass resolutions urging the suppression of expectoration.

The Identity of Human and Bovine Tuberculosis.—It must not be forgotten in view of the interest excited by the recent statement of Koch at the Tuberculosis Congress in London, to the effect that an essential difference exists between the human and bovine tubercle bacillus, that the same statement had already been made by an American and backed by almost irrefutable experimental evidence.

The monograph of Dr. Theobald Smith (*Journal of Experimental Medicine*, Vol. III., p. 451, 1898) is one of the most thorough and satisfactory of all contributions to the subject. His practical conclusions differ in this respect from those of Koch; that although the sputum (human) bacillus is incapable of finding a foothold in the bovine body, the bovine bacillus may pass to the human subject owing to its higher pathogenic power (p. 498). It would therefore be reckless to a degree to relax in any respect our efforts to control tuberculosis in cattle.

Celli's Opinion of Quinine in Malaria.—Dr. Koch also unburdened himself while in England on the subject of Malaria. That some of the Italian investigators disagree widely with Koch is apparent all through Celli's treatise. The German is quoted as saying that malarial parasites can be stamped out with quinine treatment. Celli controverts this very point very strongly. His exact words are "complete disinfection of malarial blood cannot always be obtained (with quinine), and therefore a complete rational prophylaxis by means of this disinfection, notwithstanding what Koch says about it, is not easy nor is it always possible." (Page 193).

Celli reviews the subject of the quinine treatment very thoroughly. He examined the action of quinine on the hemosporidia under the microscope, and saw that these organisms, which had been exhibiting active amoeboid movements, became still and were expelled from the red corpuscles on the addition of a trace of a solution of quinine. This drug in sufficient dose and at the right time always has a good effect in what we may call the stage of acute infection. This is in accord with world-wide empirical knowledge. Celli seems to think that the preferable time to give quinine is at the end of the attack, in the sweating stage, which is the time when there is the greatest number of young amoeboid forms in the circulating blood. Thus another paroxysm is prevented. Young amoebulae in the red corpuscles are also arrested in their development.

Before the attack, when the gymnosporidia are in the blood, quinine is but slightly efficacious against them. "It also has little effect on the parasitic forms which give rise to the obstinate recurrent fevers."

Finally, Celli says that quinine does not act on the gametes which ensure the sexual cycle in the mosquitoes. Even with large doses given hypodermically every day for a month, he says that he has not often succeeded in destroying the crescentic forms. He relies largely upon this drug, but he evidently sees its limitations. He believes that at the very beginning of the fevers the formation of gametes can be prevented or controlled.

The Cedron Seed as a Cure for Yellow Fever.—It is so seldom in this age of serum-therapy that we see a new vegetable drug extolled as a sure cure for anything, that we think such an event is specially noteworthy. In a letter in the *Public Health Reports* for July 27th, Dr. S. H. Hodgson, of the Marine Hospital Service, praises the virtues of the cedron seed as a cure for yellow fever. Dr. Hodgson writes from Progreso, Mexico. He says that in Central and South America the seed or bean of the cedron is used as a remedy for the stings of insects and the bites of snakes, and acting on this hint he used it in cases of yellow fever. The results were so satisfactory that Dr. Hodgson concluded that the cedron is as true a specific for yellow fever as quinine is for malaria. This is certainly high praise. Unfortunately, he kept no notes of the cases treated, and consequently his report is lacking in the precise details of systematic observation that we always desire to see in support of such claims. Dr. Hodgson urges that a careful investigation be made of the action of this drug, and even asks to be transferred to a yellow fever focus so that he may himself make further observations. We should remember that Peruvian bark was a long while in gaining confidence, and we should not be too skeptical in the trial of a remedy which has impressed a sense of its value upon an educated observer.

Methyl Alcohol Blindness.—Among the toxic substances having a selective affinity for the visual apparatus, methyl alcohol is now beyond a doubt deserving of decided recognition, not only from a toxicological standpoint, but from one of prophylaxis. The case of blindness from drinking methyl alcohol, that had been taken under the supposition of it being cologne spirits, as reported by Dr. Harold Gifford, of Omaha, in the *Ophthalmic Record* for July, 1901, is an indication that all packages containing methyl alcohol should be marked "Poison." The subject, while it is no longer a novelty in ophthalmic literature, sounds a warning note to the medical profession that in all cases of sudden blindness of obscure

origin, this substance should be thought of. It is not uncommon for those addicted to alcoholic beverages to procure the "next best thing" when in a locality that supplies no alcoholic drinks, and the danger to sight and even life requires that precautionary measures be observed. The case reported by Dr. G. E. de Schweinitz, of Philadelphia, in the *Ophthalmic Record* for June, 1901, shows that the pathway of entrance of the poison may even be by the lungs and cutaneous surface.

The Bed Treatment for Insanity.—In the first number of the new *Journal of Mental Pathology* (which we cordially welcome), the editor comments on this subject. As this mode of treatment is coming more and more into favor, as it deserves to do, in our hospitals for the insane, it is a good subject for brief discussion. Guislain, in 1852, was the first observer, according to Dr. Robinovitch, to record the results of what is now known as the "bed-treatment." He claimed that this treatment was of great benefit in melancholia. Hagen, in 1853, extolled it for its good effects in mania. Other alienists, among the most celebrated of whom were Griesinger and Falret, joined in this praise; the latter claiming that this treatment was especially beneficial in mania with fever. The method won its way slowly, however, and was in greatest favor in Germany. But recently the tendency is to emphasize the value of this treatment in the various forms of insanity which are attended with physical depression and exhaustion—in other words, in the majority of the acute psychoneuroses, and in some other cases. In Europe the value of this treatment seems to be generally recognized at the present time, although, as we have shown, it is not new. Magnan introduced it in its present form in France, and Joffroy has adopted it. In America some of our alienists have adopted a systematic bed treatment, which has long been familiarized among us as the "rest cure" by Dr. Weir Mitchell, and used extensively for neurasthenia and hysteria.

We have long been convinced that systematic rest cure is strongly indicated in many forms of insanity. But we also believe that it must not be given by a fixed rule, but should be modified and suited to each individual patient. Herein is where the wisdom and skill of the alienist are shown. There is no greater mistake made in the treatment of many of the cases of incipient insanity than that of giving the patient "change of scene" by hurrying him or her from one place to another. Thus exhaustion, brain-tire and confusion are increased. It were far better that the patient were put to bed. Another mistake is in postponing treatment too long. There are, however, certain auxiliary modes of treatment that should not be neglected. Among these we at-

tach first importance to hydrotherapy. With these two agents—bed treatment and hydrotherapy—we would rather take our chances than with any other two distinct methods. Massage is an important adjunct to hydrotherapy. Skilful feeding, of course, needs no championing; a good guide to go with it is an occasional blood count.

We know on good authority that in one hospital in Philadelphia they are making more and quicker cures in insanity since they introduced hydrotherapy and resort more to bed treatment. These means save the nutrition of the neurons, and that is the first and last indication in insanity. Drugs will not do it. During convalescence an out-door life, and then possibly a little change of scene, are indicated.

A Word About Temperance.—We suppose there is not a physician in the world who on principle is not in favor of temperance. In fact, we could not imagine a physician who would deliberately advocate or defend intemperance, either in eating or in drinking. The thought is preposterous. We venture to say, moreover, that there has never been a period in modern social life when a higher standard existed in the medical profession on this subject than at the present time. Intemperance in habit is certainly and fortunately a very rare vice among medical men to-day, although there are doubtless individual cases which we must all deplore. Neither public nor professional opinion will condone intemperance in physicians. While this is all true, it is equally noteworthy that the medical profession as a whole is not a supporter of total abstinence. We mean by this the total abstinence which is upheld as a moral principle and a principle of public policy—a principle which some of its extreme supporters contend is to be not only advocated, but enforced. The recent action of the American Medical Association on the subject of the Army Canteen has been variously interpreted, and we have received not a few letters on the subject. To those of our correspondents who severely criticise the Association, we must say that we believe the differences of opinion on this subject have to do as much with a question of *method* as of principle. The idea of enforcing temperance by act of Congress is repugnant to many physicians, who may be better friends of true temperance—by which we mean moderation—than are some of their critics. Intemperance in thought and language is just as possible as intemperance in eating and drinking. One of our correspondents has declared that it would be just as proper for the United States Government to maintain prostitutes for the use of the army as to maintain the canteen. We quote that sentiment merely in order to let it display its own hideousness.

Reviews.

Malaria According to the New Researches.—By Professor Angelo Celli, of Rome. Translated from the Second Italian Edition by John Joseph Eyre, M. R. C. P. With an Introduction by Dr. Patrick Manson. With Maps and Illustrations. Longmans, Green, and Co. London, New York and Bombay. 1900.

In his introduction to this important work, Dr. Manson reminds us that we owe to the Italians not only the name but also much of our knowledge of Malaria. The author of the book is one of the foremost Italian investigators of this disease. A mere statement of these facts is sufficient to indicate that we have here one of the most authoritative and most thoroughly scientific works on malaria that are now in print. The reader feels instinctively when he opens the book that he is in the presence of a fund of knowledge that is first hand, and that he is to have the advantage of following on every page the teaching of an original investigator. This anticipation is not disappointed. The book is a complete exposition of our knowledge of malaria; it is strictly scientific, replete with facts and written in a condensed but lucid style. The English-reading medical public cannot be too grateful to the translator and to Dr. Manson for putting this work into its hands.

Professor Celli's book shows from cover to cover how the field of medical investigation has changed in recent years. It is necessary now for a physician to be a naturalist in order to be an investigator in some important fields. It is needless to say that the mosquito is the central figure in Celli's book. The plasmodia come next. The order sporozoa, and its various suborders, to which belong some of the disease-producing parasites, are described. The book is very wide in its scope, beginning with a discussion of the epidemiology of malaria, and passing from this to a description of the hemsporidia. These organisms are found in the blood not only of man but also of batrachians, reptiles, birds, and mammalia other than man. The description of the parasite that infects man is complete. Celli discusses at length all phases of malarial infection. The natural history of the parasite, and of the mosquito; the conditions of environment in agriculture and drainage; the causes of predisposition or immunity; the influence of place, season, and occupation; and the various social causes. Finally in Part 4 the author takes up the difficult but vital topic of prophylaxis. It is necessary to read the book in order to appreciate the thoroughness with which Celli and the Italians have gone into this subject of prophylaxis. This is a very real problem with them, and they are studying it, not merely in the laboratories, but in the fields of the agriculturist. The book is an extraordinary revelation of a breadth of view and thoroughness of work in this domain of malaria that are worthy of the highest encomiums. From the strictly literary or academic standpoint the bibliography at the end of the book demands notice. The author states that he believes it to be an almost complete bibliography of Roman Malaria from 1600 to the present time. It is invaluable for reference to the work of recent Italian investigators.

This book should be read, of course, by every physician interested especially in malaria, but it should be read also by every physician who feels pride and interest in the progress of science in medicine. It is not a voluminous or expensive work, as it contains less than 300 pages. [J.H.L.]

Operative Surgery.—By Joseph D. Bryant, M. D., Professor of the Principles and Practice of Surgery, Operative and Clinical Surgery, University and Bellevue Hospital Medical College, Visiting Surgeon to Bellevue and St. Vincent's Hospitals; Consulting Surgeon to the Hospital for Ruptured and Crippled, Woman's Hospital, and Manhattan State Hospital, Etc. Vol. II. Published by D. Appleton & Company, New York. 1901.

It is seldom that one meets with such an eminently satisfactory work as the Second Volume of Bryant's Operative Surgery. One feature of especial importance in the work is the illustrations. No present day work on Operative Surgery can be satisfactory without the aid of good illus-

trations, and in this respect Bryant's work is very complete. Among the first chapters is one on operations upon the Esophagus. It is gratifying to find here special space devoted to description of the proper method of passing instruments into the esophagus. The general technique of abdominal operations is minutely dealt with. Every suture worth describing is here described and illustrated. One omission, however, is noted in this chapter, namely, O'Hara's forceps, which have proved so satisfactory to those who have used them in intestinal anastomosis. The author's view regarding the removal of the appendix in cases of appendicular abscess in which the general abdominal cavity is well shut off by adhesions, cannot but meet with approval by all but a few more radical surgeons. The author's attitude is that the appendix should not be removed at the primary operation, if its removal means the breaking up of all adhesions and the danger of a general peritonitis. Considerable space is devoted to the discussion of hernia. This is an excellent chapter, containing a description of every modern operation for the cure of hernia. We are glad to find in his description of hemorrhoids that Bryant heartily condemns the injection treatment. Probably no portion in the book is more complete than that which deals with operations done upon the pelvis of the kidney and the ureter. In stating that splenectomy is a more dangerous operation than splenopexy the author is not in accord with the view lately expressed by Collins Warren. The chapter on the pancreas would seem to one who has read the recent literature on this subject to be rather brief. The only omission which we have been able to detect, and which would seem to be worthy of any mention is the lack of any reference to the recent operation for hydrocele in which a simple eversion of the sac is done. The work as a whole will be found a most excellent book of reference, for the author has carefully described in each chapter every operation for the condition with which he is dealing. We cannot close a review of this work without again referring to the illustrations which render the descriptions very comprehensive. [J. H. G.]

Saunders's Question-Compend, No. 14. Essentials of Refraction and of Diseases of the Eye, with a Consideration of Ocular Injuries and the Ocular Symptoms of General Diseases. By Edward Jackson, A. M., M. D. Emeritus Professor of Diseases of the Eye in the Philadelphia Polyclinic; formerly Attending Surgeon to Will's Eye Hospital, Philadelphia; Ophthalmologist to the Arapahoe Hospital, and Consultant in Ophthalmology to St. Anthony's Hospital, Denver. Third Edition, Revised and Enlarged. 82 Illustrations. Philadelphia and London. W. B. Saunders and Company. 1901.

This little volume of some several hundred questions and paraphrased answers in ophthalmology, has through the good work of the author and the seemingly untiring energy of the publisher, reached a well-deserved third edition.

Comparison with the previous editions shows that much that is new and useful has been added. Consideration of radiography, bacteriological disease, traumatic affections, and visual and color-tests, with a chapter on the relation of the eye to the general system, has helped to make the subject-matter more complete, and to bring the work directly to date.

The book as written is a most excellent companion for the practical student in eye disease, and, as such, can be heartily recommended. [C. A. O.]

A Case of Marked Improvement of Elephantiasis Following Subcutaneous Injections of Calomel.—S. D. Schaginin (*Meditsinskie Obozrenie*, April, 1901) reports a case of elephantiasis in a woman 54 years old who also suffered from general obesity, developed during the climacterium. 14 injections of a 5% solution of calomel in liquid vaseline into the affected limbs brought about a marked improvement, the decrease in the size of the legs amounting in some places to 26%. The injections were made every 3, 6 and 8 days, 0.9 grm. of calomel having been used altogether. No constitutional disturbances were observed; the local reaction, on the other hand, was marked. The patient left before the treatment was completed. [A. R.]

Correspondence.

EYE AND EAR EXAMINATIONS OF RAILROAD EMPLOYEES.

By WILLIAM THOMSON, M. D., of Philadelphia,

Emeritus Professor of Ophthalmology, Jefferson College.
To the Editor of the Philadelphia Medical Journal.

It is to be regretted that Dr. Allport, in his reply to my plea for a hearing of July 6th upon the subject under discussion should have seen proper to use his opportunity to call attention to the personal deficiencies of his much esteemed friend, Dr. Thomson, as a member of his committee, instead of giving to our readers his opinion of the views contained in my paper, which seems to have caused unusual irritation. Some self defense seems but proper on my part.

At the meeting of the American Medical Association at Atlantic City, in the Section on Ophthalmology, I heard for the first time of this burning question, when Dr. Allport brought before the members a most voluminous report based on the replies from the officers of sixty-four railroads to eight questions submitted to them by him. The statistical information obtained through the frank replies of the roads, although impossible of comprehension at the moment, gained at the expense of much time and effort, awakened some admiration, and led to remarks extemporaneous and badly reported, which have been assigned to me. I fancied that this confidence of the officers of the roads would surely be rewarded by an effort to gain their co-operation with, or assistance to the committee of our Section with a view to perfect and adopt a system of examinations practical and satisfactory to both interests. With this hope in mind I accepted the position on the committee vacated by the wise Dr. Williams. That I was not alone in this feeling is shown by the action at the end of the debate. Dr. Lippencott, of Pittsburg, moved "That the paper of Dr. Allport be referred to a committee, appointed by the chairman, who shall use it as a basis in drawing up some practical resolutions to guide us in this work." The seven recommendations in Dr. Allport's paper were evidently not then in a form to secure their adoption by the section. Nothing further reached me on the subject until this letter, dated April 18th, came to hand.

LETTER OF DR. ALLPORT:

"You will doubtless remember that you are a member of a committee whose duty it is to report to the ophthalmological section of the American Medical Association at its next meeting at St. Paul, upon the general subject of what should be the eye and ear requirements of railroad employees, etc."

"The report has been delayed for two years at the suggestion of a member of the Committee (now resigned), pending the report of a similar Committee, which was to have been received at the last International Medical Congress, held in Paris last summer. Although using great diligence in correspondence, both to gentlemen in this country and in Europe, and in scanning all eligible literature of the proceedings of the Congress, I have failed to ascertain whether any such report was submitted or not. It appears to me therefore to be utterly unnecessary for us to further await European edicts upon this important subject, as we certainly are quite as capable of formulating intelligent opinions, as European observers."

"I beg, therefore, to secure your valuable co-operation in framing suitable resolutions to be presented to our Section in St. Paul, and to remind you that, inasmuch as we have waited till the last moment to secure tidings from abroad, our time is limited, and I hope you will at once correspond with me upon this subject, so that we may have something to start with. I beg leave to submit to you a reprint, read by myself at the Section meeting at Atlantic City, embodying certain resolutions, which appeared to me about what was needed. These resolutions may be found upon page 7. If these commend themselves to you, will you please say so? If not, will you kindly make such alterations or additions as seem to you necessary. I would suggest, however, that unless you desire radical changes, it might be well to let these resolutions stand, inasmuch as we as a committee cannot all get together, and alterations require

much correspondence, which will necessarily impede progress, and possibly prevent a unanimous and harmonious report, which is, of course, most undesirable. Do not, however, I beg of you, feel that I am undertaking to dictate in this matter, as this is far from my desire. If you really desire something different, I beg of you to so express yourself, and we will all try, I am sure, to endorse any reasonable opinions. What we desire is a harmonious and unanimous report, that may be endorsed by the Section, and later by the Association, that may be sent to all railroads on this continent.

"I trust that this matter will receive your immediate attention, and beg to remain, etc."

Then follows the report from which I quote. "Your committee, therefore, begs leave to submit to the Section the following resolutions, which have been unanimously adopted and which it is hoped will be adopted by the American Medical Association, and then correctly placed before the proper railroad authorities of North America." He explains that the Section will "superintend" this work, gain the support of the Association, and see that "the necessary literature is placed before the proper railroad authorities." Then the self-same seven resolutions of the year previous follow:

(1). "The essential principle to be advocated is that railroad corporations shall require a scientific and correct entrance examination of the eyes and ears of those employees at all to be concerned with the active operating of trains, or in giving and receiving signals.

(2). Such examinations are best made by regularly appointed eye and ear surgeons. But if such a course is not deemed advisable, the company surgeon, aided by his medical assistants, may conduct them, with the understanding that all doubtful cases shall be sent to a regularly appointed eye and ear surgeon. Non-medical men shall never conduct the examinations.

(3). There shall be two general standards of visual and aural requirements, viz., those for new men hoping to enter the service, and to be actively engaged in the operation of trains, and in giving and receiving signals, and secondly, those men engaged in similar work, who have been uninterruptedly in a company's service for five years, and who have, therefore, a right to be called old employees.

(4). New men shall be required to possess perfect color sense. They shall also have a vision of 20/20 in each eye, without glasses, and have healthy eyes, and not over two diopters of hypermetropia. They shall also hear the whispered voice at 20 feet in a quiet room, and have healthy ears.

(5). For purposes of graduated requirements old employees shall be subdivided into two classes as follows:

Class A.—Engineers, firemen, conductors, brakemen, switchmen, signalmen, switch tenders, and engine dispatchers.

Class B.—Track foremen, bridge foremen, crossing flagmen, bridge tenders, train baggagemen, telegraph operators, stations agents, and station baggagemen.

Employees enumerated in Class A shall not be retained in such position if vision sinks below 20/30 in one eye and 20/40 in the other, or if the whispered voice cannot be heard in a quiet room at 15 feet by one ear, and 10 feet by the other. Employees enumerated in Class B shall not be retained in such positions of vision sinks below 20/40 in one eye and 20/50 in the other, or if the whispered voice cannot be heard in a quiet room at 10 feet by both ears. Employees, and especially engineers and firemen enumerated in Class A, must reach the visual standard without glasses, and will not be allowed to wear distance glasses when on duty. Employees enumerated in Class B may reach the visual standard with glasses, and will be allowed to wear glasses when on duty, and will be required to do so if the wearing of glasses is necessary to bring vision up to the proper standard. All the employees shall have perfect color sense.

(6). Re-examinations shall be made of all men every three years, and after a severe illness, or accident, or any occurrence which seems to cast doubt on the visual or aural capacity of an individual. Re-examinations shall also be made more frequently on men known to be excessive users of tobacco, or to be suffering from syphilis, albuminuria, diabetes, or acute or chronic eye and ear dis-

case. Men shall always be examined before promotion.

(7). Men known to be excessive users of liquors shall not receive employment."

With no evidence, either from railroad officials, or members of our Section acting as their ophthalmic surgeons, that these resolutions if passed would be considered by those officials when enforced, if possible, by the pressure of the entire American Medical Association, I became satisfied that I could not subject my opinions to the authority of the Chairman of the Committee, and that the changes I would desire would be too "radical," and that I would be compelled to take some direct means of voicing my objections to my colleagues of the section. I therefore sent to Dr. Allport a letter, which he says he faintly remembers to have received, as follows:

Dear Doctor Allport:—

I regret that I cannot join you in the wholesale condemnation of examinations made by "non-professional but instructed persons" in your proposed report to the Ophthalmic Section at the meeting at St. Paul.

I am striving to obtain information from railroad officials to guide me in forming my own opinion. Should I attend the meeting I can have the benefit of conferring with your Committee, and with other colleagues from different sections of the country. Should I be prevented from so doing I will content myself with some expression of opinion to the Secretary of our section.

WILLIAM THOMSON.

This disposes of the hint at a want of courage or candor, but it gave notice of the arrival of a minority report under certain circumstances, and of my strong desire to express my opinion without pressure or hindrance. Inasmuch as I had proposed to railroad officers twenty years ago a series of tests for eliminating from their service those defective in sight, color sense and hearing, which had been made efficient by their wise administration, and still preserves their confidence, I felt bound to defend our mutual action against any revolutionary, arbitrary, or autocratic attempt to sweep it away.

Upon these data my minority report was based and sent to St. Paul. Should our Section unanimously adopt these views of Dr. Allport, the vast influence of the entire Medical Association would be brought to bear upon the various methods of testing now in use on our roads, and the proper "literature" would soon be applied to discredit the present tests, to place a seal of condemnation upon the results of years of slow reform; awaken the distrust of railroad officials, and cloud the title to his position of the thousands and thousands of employees, who, having passed these tests, might hope to continue their occupations in peace.

I do not desire to analyze these seven resolutions, but a glance at one section shows the want of co-operation with railroad men. The use of glasses is seldom allowed by Dr. Allport's scheme, whereas we can see by the tables of the 64 roads that there are few exceptions to their use on them. Again we find, speaking of the seventh section, "They will of course exclude a certain portion of the old employees from their accustomed occupation, but this is of small moment compared with hazarding the lives and property of the public by the retention in the service of physically incompetent men. Railroads can always, if they choose, lessen the disappointment of an old employee by transferring him to some other and less hazardous position, with a liberal salary." How do we doctors know anything about this?

My convictions are that we, as scientific men, should limit ourselves to giving our advice and support to railroad officers when they are asked for, or kindly received. Any arbitrary effort to reach them by legislation, or by overwhelming them with "literature," or by the pressure of "associations," would but defeat its object and bring upon us the mortification and disappointment so universally meted out to those injudicious friends who so kindly interfere unasked with the private affairs of others.

My suggestion to the chairman of our Section would be to secure the support of railroad officials before pressing

the conclusions of his committee upon the American Medical Association in 1902, since with the entire weight of the medical profession, it might be found impossible to exercise the least influence over the officials of our great roads against their wishes. They must and will be a party to any system that will ever be largely adopted, and each road must be left free to select the methods which its business needs will demand. Even the employment of ophthalmic and aural surgeons for example, as in the kingdom of Holland, or on any road which can or which prefers to employ them, would be proper. In marked contrast with the dogmatic tone of Dr. Allport's report I would now call attention to the one recently adopted at the annual meeting of the American Ophthalmological Society upon this same subject, which will soon be published in its transactions. I quote from it: "At the meeting of the International Medical Congress at London in 1881, a Committee of the Ophthalmic Section, presided over by Prof. Donders (in which I represented the United States) presented a report, one paragraph of which says: "That the examinations should be conducted by persons of recognized competency, under the direction of a central medical authority in each country."

In 1890, the British Board of Trade induced the Royal Society to make recommendations, the third one of which reads, "That they should be entrusted to examiners certified by the central authority."

The 10th says: "The tests in use and the mode of conducting examinations at the different stations should be inspected periodically by a scientific expert, appointed for that purpose by the central authority. No claim is made for either ophthalmic and aural surgeons or even medical men."

"Your committee feel that no attempt should be made to compel the adoption of any standards or methods of examination by means of legislation; they believe the best results will be obtained by showing the operating officers of our railroads how their service can be improved, by adopting methods of examination which will be reliable, and by maintaining standards which will be high, but not impracticable, for those entering the service, and will be the minimum of safety for old employees on re-examination."

"Railroads are justly skeptical as to the value of certificates issued by physicians not connected with the road, especially when their fee is paid by the man who employs them, and not by the company."

The report concludes with these eight resolutions:

1. That all railroad employees concerned with the movement of trains or reading of signals be carefully examined as to their acuteness of vision, color-perception and hearing.

2. That a trained ophthalmic surgeon be selected by each company, who shall instruct and examine the men selected by the company to make these tests, shall recommend the standards and methods to be used, shall see that the equipment furnished to each examiner is sufficient, that it is kept in proper order and renewed when necessary, and who shall be the authority to whom the doubtful cases shall be referred for final settlement.

3. That the acuteness of vision shall be tested by the test types of Professor Snellen, or those which conform to his standards.

4. That the following minimum requirements be adopted for acuteness of vision.

5. That the color-perception be tested by means of the colored worsteds of Professor Holmgren, preferably with worsteds tagged for purposes of record; also, that in every case an additional test be made with a lantern showing a number of colored lights, which can be varied in their size and intensity.

6. That no one shall be considered to have satisfactory color-perception who calls a red light green, a green light red, a red light white, under any of the varying conditions of the lantern test; or who selects with the green and also with the rose test skeins the characteristic confusion colors.

7. That the hearing be tested by the spoken word of the examiner and by a watch or acoumeter, and that for entrance to the service a candidate be required to repeat correctly words or numbers spoken in an ordinary con-

versational tone at a distance of twenty feet; or, for re-examination, at a distance of ten feet.

8. That re-examinations be made at intervals of three years, also before promotion, and oftener in special cases, where necessary.

9. That a copy of this report be sent to the Secretary of the American Railway Association for transmission to their committee on safety appliances.

The 9th was not approved by the Society, but is given here to show how carefully its members preserve their own dignity, and avoid pressing their opinion upon railroad officials. It was believed that the railroad officers would have knowledge of the Society's action, and would be free to act or not, as they considered best, without any solicitation.

In 1881 the Pennsylvania railroad through the labors of its transportation society, composed of its most able division and other superintendents, in conjunction with the writer, put in force a system with the examiners chosen from employees instructed by the ophthalmic surgeon. It is still in force on 15,000 miles of track with 81,000 employees and has been adopted by many other great roads controlling an estimated mileage of 150,000 miles.

One instance of the evolution of our present method, which I proposed in my first paper as a proper object for any reformer, may be found in the adoption in the report of the lanterns invented by Dr. Williams and myself, which by supplementing the defects of the wool tests, will go far toward rendering them of secondary importance, and making the tests for color defects simple enough for any tyro.

I am advised that the feeling in the section meeting at St. Paul was far from unanimous in favor of Dr. Allport's Committee, and I should think that any persistent effort to suppress debate, keep out information, or bring opponents into disrepute by personal criticism, would be resented as beside the issue, and unworthy of the great interest of a public nature now involved. When the final action is taken at the meeting in 1902 a study of the two rival "recommendations" may after all only illustrate the psychological difference between the Imperialistic and the Democratic temperaments.

Systoscopy in the Study of the Chronic Nephritis of Children.—In *La Presse Medicale* (1901, No. 31) Marfan describes the application of systoscopy to the study of chronic infantile nephritis. It is as yet hard to draw any conclusions from the results. He reports the case of a boy of 8, with a nephritis of unknown origin which has lasted 15 months. Erysipelas, pneumonia, and pleurisy ran their course, yet the nephritis continued unaffected. There was from 2 to 5 g. of albumin to the liter of urine, with the urine reaching 1500 g. daily. Edema persists, while anasarca and ascites appear from time to time. Chronic infantile nephritis generally comes on insidiously, after the age of 6 years. Granular casts are found in varying quantity. Emaciation and pallor become marked. Cardiac and uremic symptoms are generally lacking. These cases usually last years, growing better or worse, yet always showing some albumin in the urine. A cure, while possible, is very rare. Yet most cases live to manhood with exacerbations and remissions. Pathologically but two forms of chronic nephritis exist, primary renal sclerosis, very rare in children, and diffuse parenchymatous nephritis, common before puberty. Neither Bouehard's method of measuring the urinary toxicity nor methylene blue has been a success. Systoscopy, the idea of Raoult, of Grenoble, is the latest method to be tested. It shows, in this case, that the renal permeability is normal. The experiments, which were performed by Léon Bernard, are given in full. He believes that the renal permeability is normal or even increased in the early stages of parenchymatous nephritis. But the kidney probably has other functions, as yet unknown, which, when disturbed, cause the production of uremia. Milk diet should be absolute during the exacerbations, but mixed soft diet is better during the remissions. If the patient can digest it. This will be shown by the amount of albumin in the urine. As diuretics, Marfan advises lactose and theobromin. Should uremia occur, the patient must be bled. [M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

The Alvarenga Prize of the College of Physicians, of Philadelphia, for this year has been awarded by the committee to Dr. George W. Crile, of Cleveland, Ohio, for his essay entitled: "An Experimental and Clinical Research Into Certain Problems Relating to Surgical Operations."

Dr. J. L. Forwood, of Chester, Pa., has been reappointed a member of the State Quarantine Board.

Susquehanna County Medical Society.—Following are the newly elected officers of the Susquehanna County Medical Society. President, Clarence N. Vanness, Hallstead; Vice-President, John G. Wilson, Montrose; Secretary, Edward R. Gardner, Montrose; Treasurer, Calvin V. Halsey, Montrose; Censors, Abram E. Snyder, Susquehanna; John G. Wilson, Montrose; Charles A. Johnston, Harford.

The Dissemination of Tubercle Bacilli by Cows in Coughing a Possible Source of Contagion.—As quoted in the *Bulletin of the Bacteriological and Pathological Laboratory of the Delaware State Board of Health*, Newark, Del., Mazilek P. Ravenel (*Univ. Med. Mag.*, Nov. 15, 1900; *Med. Rec.*, Dec., 1900) of Philadelphia, gives the results of numerous experiments relating to this subject. In order to collect the sputum from tuberculous cows he made use of an ordinary nose-bag, near the bottom of which is placed a shelf of soft pine wood, sterilized by steam heat each time before using. The wood catches the smallest particles ejected by the cow during the act of coughing. The more solid particles may be removed by a platinum needle for experiment. Tubercle bacilli have been detected in the bronchial secretions of every tuberculous cow on which the experiment has been tried. Of forty-five guinea pigs inoculated in the peritoneal cavity with the tuberculous mucus, twenty-three died within a few days, most of them with peritonitis, too early for the development of tuberculous lesions. Of the remaining twenty-two, eleven or fifty per cent. became markedly tuberculous. Fourteen guinea-pigs were exposed by means of a special nose-bag directly to the breath of the tuberculous cows, and after several weeks were killed. No evidence of tuberculosis could be detected in any of them.

The Lehigh Valley Medical Association held its mid-summer meeting at Mauch Chunk, July 25, 1901, with about sixty in attendance. Guests present were Prof. Roswell C. Park, of Buffalo, N. Y., and Prof. W. J. Hearn, Dr. Boardman Reed and W. B. Atkinson, of Philadelphia. After some formal work the President read the annual address. Dr. A. A. Seem, of Bangor, delivered the presidential address. He selected **Diagnosis** as his theme, because a physician, to be a good physician, must be a good diagnostician. He who diagnoses well, treats well. The need of proper diagnosis is seen on every side. Cripples, deformities, mounds in the cemeteries are the signs. Tuberculous joint, mistaken for rheumatism known too late. Prof. Da Costa obtained his great reputation by his wonderful power of diagnosis. The essentials are a thorough knowledge of anatomy and pathology. Symptoms are mistaken for the disease itself. Hence the false systems of medicine of the past. Modern pathology has changed all this. Thanks to such men as Koch and his compeers. Clinical experience is demanded. Diagnosis is an art, but is becoming more and more scientific. Recently diagnosis has progressed by leaps and bounds. Careful investigation is demanded into nativity, heredity, environment, habits, etc. An accurate account must be had. Next the evolution of the attack. Cultivate your powers of observation, that they may become acute. Pay attention to little things. Let nothing escape. The careful and painstaking are more sure of success. Bedside observation is our mainstay. Next the importance of laboratory methods, this without prejudice to what has just been said. The microscope and chemical reagents are imperatively needed. Then the nausea, headache, dimness of vision, dyspnea, if due to renal lesion, are recognized, or typhoid with nephritis are ascertained and properly treated. The condition of the blood is fully known, iron is given or withheld scientifically. Bacteriology gives us the Widal test. The sputum shows the condition of lungs, especially in tuberculosis. Also in diphtheria we early know the true

condition. Correct diagnosis at the earliest possible moment is gained to the advantage of the physician, the patient and the community. A corner of the office may do duty as a laboratory. We may call to our aid the services of others if too busy to attend to all these points. Often we may have the aid of a state or local board of health in such work.

Prof. Roswell Park, of Buffalo, read a paper "The Evolution of the Surgeon from the Barber." Nothing in the tomes of the past will be found more curious than the connection between the craft of the barber and that of the surgeon. Even after studying history, the predominant yet concealed reason for this will be missed. Women were licensed to practice surgery in the 14th century, but denied that right in the 19th. Specialties were recognized in the 16th but lost their dignity later. Medical education has wonderfully progressed since the teaching of apprentices who were to be comely, able to read and write, wear no beards and be well punished when at fault. Remember, there was a time when bleeding was deemed necessary for all ailments. After the church condemned the shedding of blood by any of her officials, it was natural to turn to the barbers who were supposed to be dextrous in this way. Added to this was their care of wounds, dressing of fractures, etc. All former military surgeons were from this class. Thomas Gile describes in the armies of Henry VIII these surgeons who made great pretences, but by cross questioning showed how little they knew. The barber surgeon in Germany still is a common figure, also in Russia, where educated surgeons are still few for the vast population. Again the church imbued men's minds with a horror of a dead body and of those who studied anatomy, and dissectors were exposed to insult and even death. Hence only intense desire for knowledge permitted such instruction. In the middle ages, the great school was situated at Salerno near Naples. Among its ordinances one read "That the person examined must be 21 years of age and have studied physic five years. He must agree to be obedient to the society, learn anatomy one year, refuse fees from the poor, and share no gains with apothecaries. These last deserve attention at the present day. Even the site of the building is lost and no one seems to know where it stood. In 1240 Emperor Frederick II was the patron of this college. One of his enactments says: "Since it is possible for a man to understand medical science only if he has previously learned some logic, we ordain that no one shall be permitted to study medicine until he has given attention to logic for at least three years." "No one shall be allowed to practice until he has submitted certificates in writing of the teachers of the faculty of medicine that he has spent at least one year in that part of medical science which gives skill in the practice of surgery, that in the college he has diligently and especially studied the anatomy of the human body, and that he is also thoroughly experienced in the way in which operations are successfully performed and healing afterwards brought about."

In Great Britain medical men were first called leeches, later the clergy introduced books from Rome and almost every monastery had some brother possessed of knowledge in medicine. Salerno gave great impetus to the study of medicine even before William the Conqueror, this was strengthened by the influence from Naples and also from Montpellier. For centuries, the Catholic clergy were almost the only physicians, which became so lucrative that many monks abandoned their monasteries, and applied themselves to medicine. This compelled the decree of the Council of Tours in 1163 prohibiting them remaining away and forbade them to teach the practice of physic. Even bishops, etc. acted as physicians to kings and princes, preaching, practicing, acquiring riches and honor. Pope Boniface early in the 14th century issued decrees, formally separating surgery from physic, and forbidding the priests from practicing the former. This, in spite of the fact that long before Pope Innocent III decreed that no ecclesiastical was to undertake any operation which involved bloodshed. Thus it was that surgery was abandoned to an ignorant laity. The Jews were next in their learning, having intercourse by their nomadic life with all nations, denied to others, many studied medicine and practiced among Moors and their own race. The priests became jealous of Jewish physicians and of lay surgeons, and endeavored to obtain from Rome a law that no such might

give medicine to a Christian. But so celebrated were these Jews that the power of Rome could not exclude them. At first in England the priests were not disposed to practice medicine, though later they became so much interrupted in their duties that the Pope looked upon this as detracting from clerical dignity. To the church then we owe this abandonment to the ignorant. The sway of the church over the barber surgeons long remained. The surgeons and barbers were licensed by the Bishop of London or the Dean of St. Paul's, an acknowledgment that they belonged to a learned profession. In the old London Company of Barbers and Surgeons the division was maintained. As the surgical section became more skilled it tended to become a science and soon the surgeons demanded a separation, giving up all the property and obtaining a separate charter, which led to the incorporation of the Royal College in 1784. In France the hairdressers were formally separated from the barber-surgeons by Louis XIV. In 1308 the London Company of Barbers was formed, in 1462 they received a charter. In 1540 they were united with those who practiced purely as surgeons. Later, they obtained exemption from bearing arms and serving on juries. In 1540 Parliament allowed them yearly four bodies of criminals for dissection, supposed by some to be the first official authorization of provision for dissection. In 1375 the Barbers' Co. was divided into two sections, respectively those who practiced shaving and those who practiced surgery. In 1460 the surgeons became the Guild of Surgeons and became one of the livery companies of London. Similar separation took place in the guild of weavers, into the Woollen Drapers and Linen Armourers, the latter becoming later the wealthy and powerful Company of Merchant Tailors. A statute of Henry VIII enacted that no one shall occult any practice of surgery, letting blood, etc., except drawing of teeth. In Wood's history we read that September 10th, 1348, appeared a number of men named, and with them a whole company of barbers within the precincts of Oxford, intending to bind themselves in unity and love, 'brought with them certain ordinances and statutes in writing for the weal of the craft of barbers, desiring that the chancellor would examine, correct and apply the seal of the University. Thus was formed the corporation of barbers, the surgeons, the wafers and the makers of singing bread. When at last the cappers or knitters of caps were united to them in 1551 the barbers and wafers abrogated their charter and took one in the name of the city till 1675, when they received a charter from the University. He traced in a most interesting way these guilds of barbers in several cities to the 18th century, when medicine and surgery were abruptly separated, the latter being placed entirely in the hands of the barbers. The greatest contempt was shown for one who attempted any surgery, thus, if, while a nobleman was being bled, he received the slightest harm, the barber was heavily fined, and if the gentleman died, the culprit was given to the relatives to be dealt with as they desired. Even while the church did not hesitate to inflict bloody punishments for heresy, the monks were forbidden to perform any surgical operation, since the church had a horror of shedding blood. The truth is, this was the result of superstition and ignorance, the former from tradition and custom, the latter due to the lack of anatomical knowledge, itself due to the denouncement by the church of the profanation of a dead body. For hundreds of years, monks were not allowed to wear a beard, which necessitated the employment of tonsors, who also performed operations as bleeding, bandaging, etc. Such were not eligible to membership in any fraternities. In 1466 the Emperor Wenzel was rescued from prison in Prague by the daughter of a bathkeeper; he made her his mistress and declared both barbers and bathkeepers respectable, but having lost his position, he decreed their profession an art and gave it position above any they really made eligible to the guilds. In 1696 Leopold decreed their profession an art and gave it position above an apothecary and they were elevated to the making of ointments and plasters.

As surgery has as a profession to thank the existence of man with a beard, so the European continent of the 11th century may thank the crusaders for having necessitated the existence of the bathkeeper, because of the leprosy they brought from the East. At this time were founded the three orders for the care of the pilgrims and injured

soldiers, the Knights of St. John, the Knight Templars and the German Order. All this would be very interesting but not appropriate here. These grew into most despotic bodies, and at one time had in Europe 2000 hospitals, and Louis the Saint found one for those blind from Egyptian ophthalmia. Again at this time there was great neglect of cleanliness even among the upper classes. The hospitals for lepers being insufficient, bath houses were built and keepers engaged to prevent the spread of the disease. As bathing became less necessary, the bath-keeper limited the barber, though not till much later was he allowed to treat wounds and chronic diseases. Now he was supposed to be somewhat of a linguist and know a little botany, and he used the bodies of swine on which to learn anatomy. Erhardt said the sixteen virtues of a barber were fear of God, he should be careful, prudent, temperate, ready to use both hands equally; he said arrogance seems most prevalent among barbers, they were proud animals. He was surprised at the envy and malice between bathkeepers and barbers and says both should consult physicians and other masters. The first Master of the London United Company of Barber Surgeons was Thomas Vocary, Sergeant-Chirurgion to Henry VIII, and overseer of all officers within the newly restored hospital of St. Bartholomew. He was author of two works on anatomy, and declares three points very expedient for all men to know who intend to use the mystery of chirurgery: to know what chirurgery is, how to choose a chirurgeon, and what properties a surgeon should be endowed with. St. Cosmo and St. Damien were the saints of the barbers, supposed to be two physicians who practiced in the early part of the 4th century and suffered martyrdom. Among the regulations were that he should not take any child to be an apprentice unless presented to the officers of the craft to examine if he be vexed with gout or leprosy or maimed or disfigured in any part. At this time if a boy could write a little and read a little Latin no one dared refuse him. He went from house to house sharpening knives, spreading plasters, picking lint, caring for children, doing menial work, using the same light as the house-maid, it would have been disrespectful to the wife of the master to use any other. After years of this he was taken to see patients, taught to bleed, cup, leech, extract teeth, administer clysters. Anatomy he did not learn, as his master could not instruct him. He was supposed to pass an examination, but usually his master was too lazy to examine him. He then presented his master with some silver instruments and was dismissed with an injunction to be thankful that such a miserable creature had been taught to shave a beard, etc. He was now a journeyman, living still at the house of the master, not allowed to marry, later receiving a paltry amount, got his dinner free. Study was out of the question, he served the community as a tale-carer. After some years he applied to the authorities for a certificate, passed an examination before the physicians of the district. Prussia first regulated medical practice. Thus no temptation caused many to enter the ranks and hence no good surgeons were found in Germany so late as 1790. It was general lament that German surgeons were educated in barber shops. They could not carry a word nor go in the society of physicians and often were bitterly persecuted. At the beginning of the present century scarcely any physician could diagnose a surgical case. Von Siebold deplored the position of the surgeon, his large military experience had shown him the difficulties before he could enter society, though ambitious, and his high motives were scorned. Even the peasantry were opposed to all operations and often he removed patients to other towns to operate on them. Still it cannot be wondered at, when the barber would drop his knife to treat a fracture, hernia or an obstetric case. He was compelled by the State to call in a physician for complicated cases, hence such consultations resulted in quarrels, etc. In the capital city of Prussia in 1725 only 20 German and 6 French surgeons were allowed to practice. Till 1808 every German surgeon carried on a medico-legal business which was later separated from his surgery. In 1782 there were three classes, from the lower one might be promoted to a higher after an examination. In Austria, in 1805 there were doctors of surgery required to show a general knowledge of medicine who had the same rights as a physician; there were also medical surgeons who practiced under restrictions, and bathkeepers for minor sur-

gery. An official fee bill in Prussia in 1815 shows the highest fee charged was for a lithotomy in adults, about \$35, while the majority of operations ranged from \$5 to \$15. Then money was of greater value than now. The church brought about the separation of surgery from medicine, not a condition of Greece and Rome. Even the University of Paris refused to admit a student who did not foreswear the study of surgery. Many considered surgery too odious a study, others had a prejudice against it, hence they had no social position. In 1774 Mederer was made Professor of Surgery in Freiburg. He delivered his opening address on the wisdom and necessity of combining medicine and surgery. Hence he was insulted by the students, abused by the surgeons, and threatened with personal attacks. He maintained his position, fought the prejudice, and 22 years later left Freiburg with public opinion so changed that he was serenaded and the students apologized for what their predecessors had done. Then the constitution of France contained a clause combining medicine and surgery and the Royal Sanitary Commissioners of Vienna unanimously resolved in favor of such union. This movement was continued by Richter, von Siebold, Loder and others. Only 100 years ago the Electoral Academy of Erfurt offered a prize for the best essay on: "Is it necessary and possible to combine medicine and surgery theoretically as well as practically?" Fourteen papers were submitted, twelve were in favor of union. Yet the Academy awarded the prize to the only writer who had opposed the union. His reasons were puerile. Nevertheless a great step had been taken, the guilds and fraternities of barbers and bathkeepers were abolished and Vienna in 1783 took the lead. It was then declared that shaving was the business of the hairdresser and that barber surgeons must attend lectures in surgery and anatomy. Bavaria followed in 1804 and then Prussia. By 1811 the barber license was no longer essential for the practice of surgery. In the 17th century the German surgeons held simply the position of barbers. They began life by cutting hair, shaving, cupping, bleeding, later they dressed wounds and ulcers and were permitted to treat fractures and dislocations. Dresden and Hanover began to improve the education of the barbers about the middle of the 18th century, while in Berlin in 1713, first was opened an anatomical theatre for instruction of barber surgeons attached to the army. A military medical school, the Josephineum, was opened in Vienna in 1781, but the regular surgical clinic of Vienna was not instituted till 1774, while Germany's greatest teacher of surgery, Richter, did not begin formal clinical instruction in Göttingen till 1781. Thus we see that systematic surgical clinics are institutions a little over one hundred years old.

The election of officers for the ensuing term was made: President, Charles P. Knapp, Wyoming; Vice-Presidents, J. A. Horn, Leighton; H. Reeser, Reading; W. H. Hartzell, Allentown; E. M. Green, Easton; Secretary, Charles McIntire, Easton; Assistant, W. P. Walker, South Bethlehem, and Treasurer, Abraham Stout, Bethlehem, with an Executive board from the several counties.

Vital Statistics of Philadelphia for the week ending July 27, 1901:

Total mortality	461	
	Cases.	Deaths.
Inflammation of the appendix 5,		
bladder 3, brain 11, bronchi 3,		
kidneys 21, tonsils 1, lungs 10,		
peritoneum 1, pleura 2, stomach		
and bowels 30, nerves 1		91
Marasmus 18, inanition 26, debility 6		50
Tuberculosis of the lungs		55
Apoplexy 13, paralysis 7		20
Heart-disease of 22, fatty degeneration of 2		21
Uremia 10, Bright's disease 8		18
Carcinoma of the bowels 1, breast 2, stomach 3, uterus 3, face 2,		
liver 1, rectum 1		13
Diphtheria	31	4
Brain-abscess of 1, disease of 3		4
Typhoid fever	74	7
Old age		10
Scarlet fever	28	2

Cases. Deaths.

Alcoholism 2, asthma 2, burns and scalds 2, casualties 9, child birth 1, cholera infantum 66, cholera morbus 2, cirrhosis of the liver 1, convulsions 11, convulsions, puerperal, 1, cyanosis 3, diarrhea 3, drowned 7, dropsy 1, dysentery 2, epilepsy 1, erysipelas 2, fever, gastric 1, hernia 1, hemorrhage from stomach 2, hemorrhage from uterus 2, homicide 1, intussusception 1, leukemia 1, obstruction of the bowels 1, sclerosis, arterial 1, liver 2, shock, electric 1, septicemia 3, smallpox 1, suicide 2, sunstroke 9, teething 3, tetanus, traumatic 1, ulceration of the stomach 2, unknown coroner case 1, whooping cough 8

163

Correction.—We are informed from the Treasury Department that in the Health Reports for the week ending July 15, the 66 cases and 33 deaths of smallpox charged to Nebraska City, Neb., should have been charged to New York City.

NEW JERSEY.

Mercer Hospital, Trenton.—The Board of Managers of the hospital has appointed the following staff: Consulting surgeons, Drs. Samuel W. Latta and Thomas H. Mackenzie; consulting physicians, Drs. William Elmer and Cornelius Shepherd; gynecologist, Dr. Joseph B. Shaw; pathologist, Dr. Irenaeus M. Shepherd; attending surgeons, Drs. John Bruyere, Nelson B. Oliphant, John S. Jamison and William McD. Struble; attending physicians, Drs. Irenaeus M. Shepherd, William A. Clark, Charles J. Craythorne and Charles F. Adams; medical director, Dr. William Elmer; resident physician, Dr. Frank Harris, and registrar, Dr. George H. Parker.

NEW YORK.

A New Aqueduct for New York City.—An aqueduct from Lake George to New York City is contemplated for the purpose of affording a pure water supply to New York City.

Differs from Dr. Koch.—James Law, director of the New York State Veterinary College of Cornell University, does not wholly agree with Prof. Koch in his conclusion that the bacillus tuberculosis which is found in cattle could not be transferred to human kind. While Law admits that the bacillus of tuberculosis when cultivated in the human body and in bovine acquires qualities which are characteristic of different habits, it is nevertheless too early to take the absolute stand attributed to Dr. Koch, that the bacillus in one genus is radically different from that found in the other. He believes that tubercle bacilli simply acquire new habits which vary according to the genus in which they thrive.

Outdoor Treatment for Tuberculous Insane Successful.—A despatch from Albany states that a system of outdoor treatment for insane tuberculous patients has been in operation in the Manhattan State Hospital for the last two months, and that the State Commission reports that it has been attended with gratifying results. About sixty patients have been quartered since July 1 in the wooden floored tents on the hospital grounds. The patients have lived and slept in the tents. The result has been that old and feeble patients are now able to walk and care for themselves.

Bubonic Plague at New York.—It is reported that according to the report of Surgeon-General Wyman, sent from Washington, to Dr. Doty, health officer of this port, the disease from which Rabyana, a British Indian, who was stoker on the steamer Hohenfels, is suffering, is the bubonic plague. When the Hohenfels arrived here from Calcutta, and other Oriental ports, on last Monday, she was detained at Quarantine for the usual examination of the vessel and crew and the disinfection to which all vessels are subject that

arrive from ports liable to cholera and other infectious and contagious diseases. Rabyana, who is 20 years old and married, had a swelling of the glands of the groin. He was removed to Swinburne Island, where Dr. Doty performed an operation to obtain the material necessary for a thorough bacteriological test to discover the nature of the disease. A part of the official statement given out by Dr. Doty as the result of the test was as follows: "Specimens were taken from the gland and examined at the quarantine laboratory, and an organism believed to be the plague bacillus, was found. Upon the discovery, I sent the bacteriologist of this department to Washington with the specimens referred to. After an examination by Drs. Geddings and Rosenau, of the Marine Hospital Service, Surgeon-General Wyman reported to me that the result of the examination confirmed the diagnosis made in the laboratory of this department. The case is a very mild one."

Dr. William Browning, who has served in the capacity of librarian of the Medical Society of the County of Kings for the last ten years has been elected president of the society at the last annual meeting. During the incumbency of Dr. Browning the collection has grown from a scant 4000 volumes to a total of 30,000 bound volumes and 15,000 pamphlets. In the January-February issue of *Medical Libraries* appeared a biographical sketch of Dr. Browning.

North American Indian Obstetrics.—One interesting event of the Pan-American Exposition, states the *Southern Medical Journal*, was the birth of an Indian papoose in the grounds, at which one of the internes of the hospital was present. The squaw squatted on the ground in an upright position, while another, standing behind, kept up an intermittent compression on the uterus in front. On examination the os was found fully dilated, and a few moments later a single pain resulted in the expulsion of the child. The next day the woman was up and engaged in her ordinary occupation. How different from her "pale-faced" sister.

WESTERN STATES.

The Recent Smallpox Epidemic at Garrett, Ind.—Dr. Chas. I. Stewart, health officer at Garrett, Ind., reports that the epidemic of smallpox in his town in May was limited to thirty cases, and that quarantine and vaccination quickly brought the disease under control.

Vaccinated Persons Were Not Attacked.—The *Monthly Bulletin* published by the State Board of Health states that Dr. Cummins, health officer of Jackson County, Ind., has made particular examination in his county of the cases of smallpox, and reports as follows: Smallpox appeared in Jackson county in January, 1900. There were eight cases that month, forty-four in February and seven in March, making fifty-seven cases. There were no deaths and not one of the persons affected was ever vaccinated, while scores of exposures of vaccinated persons never developed a case. In a certain family the father, mother and daughter had been successfully vaccinated, but five grown children had not been. The latter all had smallpox, but the first three nursed them through the attack and remained well.

Donations to the National Jewish Hospital.—The National Jewish Hospital, located in Denver, Col., has been given \$25,000 by W. Guckenhims' Sons, of New York, and \$5,000 by S. Grabfelder, of Louisville, Ky.

The Nebraska State Medical Society has succeeded in getting an appropriation from the Legislature to classify and take care of its library.

SOUTHERN STATES.

The Texas Medical Law.—The new Texas medical law which went into effect July 1 requires examination by the State Board as a condition to practice medicine. Physicians registered in States where the requirements are equivalent to those of Texas may secure a certificate without examination by paying the usual fee.

A Reactionary Dictum.—The *Public Ledger* states that the announcement of Dr. Koch's discovery of the immunity of human beings from infection from the tuberculosis bacillus that infects cattle has been received at the Department of Agriculture as a radical and reactionary dictum which is, as one of the Department officials remarked, "important

if true." The discovery comes as a surprise to the Government scientists and they are all hard at work to get a grasp of Koch's method of determination and master his theory. Thus far none of them has vouchsafed an opinion as to the merit of the alleged discovery. As a matter of fact, the utterances of the Department have been uniformly opposed to Koch in his outgivings on the subject. Yet the Government scientists by no means underrate his eminence and attainments in his special work. All this line of experimentation, so far as it is carried on by the Department, is an industrial question. It is done under the direction of Dr. Salmon, the Chief of the Bureau of Animal Industry, and the policy of the Government is only to keep a sharp control of the avenues by which animals infected may be brought into the country or moved from one section to another to the danger of districts wholly exempt or nearly so from the disease. The Bureau sends out annually from 35,000 to 40,000 doses of tuberculin, and leaves to the State officials largely the matter of discovering and stamping out the disease among cattle.

Dr. Welsh Believes that Dr. Koch's Facts are Antedated.—Dr. William H. Welsh, Professor of Pathology at the Johns Hopkins University is credited with stating that the credit for the discovery of the similarity between the bovine tubercle bacillus and the human tubercle bacillus should be given to Dr. Theobald Smith, of Boston, a member of the Massachusetts State Board of Health and a Professor in Harvard University who published in 1898 an exhaustive paper on this subject in the *Journal of Experimental Medicine*.

CANADA.

(From our Regular Correspondent.)

The Twenty-first Annual Meeting of the New Brunswick Medical Society was held on the 16th and 17th of July at Monckton, the Vice-president, Dr. S. C. Murray, in the chair. The following well-known practitioners of that province contributed papers: Dr. J. H. Ryan, Sussex; A. J. McCully, Monckton; G. A. B. Addy, St. John; J. C. Webster, Chicago; J. R. McIntosh and W. L. Ellis, St. John. The officers elected for the ensuing year are as follows: President, Dr. S. C. Murray, Albert; Vice-President, Dr. G. A. B. Addy, St. John; corresponding secretary, Dr. J. O. Calkins, Sackville; Recording Secretary, Dr. W. L. Ellis, St. John; Trustees, Drs. R. L. Botsford, R. S. Thorne and J. W. Bridges. The next annual meeting will be held at St. John.

A New Hospital is shortly to be erected at St. Stephens, N. B. Lady Tilley, wife of the late Sir Leonard Tilley, at one time governor of the province, is at the head of the movement and is devoting her entire attention and energy to the project. A meeting was lately held at her residence, "The Cedars," when representative citizens of St. Stephens were present. The Chipman heirs devoted their old home to the object, which involves the dedication of the entire property with all fixtures to the purpose of a hospital. It is expected that the equipment will be provided by public subscription, while maintenance will be provided for by a grant from the local government. During the meeting it was announced that already five beds have been endowed and several others practically guaranteed. One of the members of the government who was present assured them that a grant could be relied upon.

A New Hospital for Contagious Diseases has long been desired at the Capital, Ottawa, and it is stated that the recital of the ineffectual attempts to get a pest house for that city would make a fitting companion volume to Eugene Sue's *Wandering Jew*. Some years ago a site was selected on Porter's Island in the Rideau River and a group of cottage hospitals were erected at the cost of \$15,000. No sooner was this accomplished than the provincial health authorities condemned the site on account of liability of inundation through spring freshets. Several sites were chosen in succession, one being in the proximity of the official residence of the Governor-General, but Lord Minto objected so strongly that the City Council gave way in deference to His Excellency's wishes. A few weeks ago the Council suddenly came to a decision to purchase a property in the rear of the Protestant General Hospital and agreed to pay \$31,000 for it, an amount double the assessed value of the property. Rumors were rife on the streets that there was a "deal" on, and that members of

both City Council and the Board of Health were implicated in the transaction. The result is that the Mayor has notified the City Solicitor that an investigation would be the proper thing in order; so another effort will be made by Ottawa to find out where they are at with regard to this very important question. In the meantime there is an alarming prevalence of contagious diseases and a great want of a proper place for isolating these cases.

The Provincial Board of Health of Ontario has made the health of employees in the lumbering and mining camps of the province the subject of a special regulation. In these unorganized districts there is a population of 100,000 scattered over more than four hundred townships, which extend 1200 miles from the Ottawa River to the eastern boundary of the province of Manitoba. According to these regulations, the owners, managers or foremen of these mining camps, lumber camps or other such like places, as sawmills, smelting works, railway construction camps, will be held responsible for the enforcement of all provisions of these regulations which have regard to the sanitation of these places and the health of their inhabitants. Special request is made that prompt notice be given the secretary of the Board of Health at Toronto of any outbreaks of contagious diseases and all unsanitary conditions discovered in these camps. The regulations are the outcome of the expensive outbreak of smallpox which the Board of Health has lately had to contend with in different northern sections of the province.

The Health Department of the City of Montreal had a very busy time of it during the month of June. Infant mortality was exceedingly high, one week running over two hundred in children under five years of age. During the month there were 165 new cases of contagious diseases reported, forty-four of these being only made known to the department at the time of death. Typhoid fever was the most prevalent. There were eighty cases, with fourteen deaths. Measles came next in order with thirteen deaths out of forty cases reported; scarlet fever, thirty-nine cases with eight deaths, diphtheria with five deaths among eighteen cases. Seventy-eight patients were admitted to the Civic Hospitals; twenty-nine were discharged as cured, four died. The question of improving the city's milk supply was taken up recently by the Hygienic Committee; and the Committee will try to institute a new mode of indicating to citizens the best sources for the purchase of milk.

Tuberculous Immigrants Barred.—Immigrants suffering from consumption will be barred from entrance into Canada along similar lines to those inaugurated by the United States Immigration Bureau.

Dr. Thomas H. Lunny, recently graduated from McGill University, and a native of St. John, N. B., has been appointed medical superintendent of the General Hospital of that city in place of Dr. John McCauley, who has resigned.

Dr. A. T. Stanton, late of the house staff of the Toronto General Hospital, has been appointed surgeon of the Canadian Pacific Railway Steamer "Empress of China," of the Pacific fleet.

Dr. Frederick Montizambert, director-general of public health at Ottawa has been delegated by the Canadian Government to attend the conference on tuberculosis in London.

Dr. J. R. Jones, Winnipeg, will deliver the address in surgery at the coming meeting of the Canadian Medical Association in August: Dr. O. H. Jones, Victoria, B. C., the address in medicine, and Dr. Thomas S. Cullen, Johns Hopkins, the address in gynecology.

Dr. Alexander Primrose, professor of anatomy at the University of Toronto, will deliver the address in surgery at the meeting of the Maritime Medical Association at Halifax, N. S., of which Dr. W. S. Muir, of Truro, N. S., is the president.

MISCELLANY.

New Japanese Death Penalty.—The Japanese have suggested an improved method of execution which experiments upon animals seem to show is quite painless. The condemned person is shut in a chamber from which the air is rapidly withdrawn by powerful pumps, death ensuing immediately.

Beri Beri Due to Mouldy Rice. Dr. Charles Hose, of Sarawak, after many experiments, has formed the theory that the disease beri arises in tropical regions from the consumption of mouldy rice. Dr. Strangeways Pigg, of Cambridge, has expounded the theory in England.

Plague Raging in Cape Town.—The bubonic plague is developing seriously in Cape Town. Fifteen new cases were officially reported, and ninety-seven other persons were isolated because of having come in contact with the victims of the disease. Recently two colored persons who had been attacked by the plague died in the streets of Cape Town. A European died while being removed to the hospital. The malady is reaching the more prosperous classes.

Plague in Egypt.—The Agent and Consul-General at Cairo, Egypt, states that the virulent and destructive type of the recent epidemic of bubonic plague had caused general apprehension and alarm throughout Egypt. In the Zagazig and Minieh epidemics, the total number of cases of plague officially reported in these two towns the past week was 23, 21 of which were at Zagazig and 2 at Minieh. Of these cases, 16 were admitted into the hospital and 5 were found dead outside of the hospital at Zagazig. Besides, out of the 15 admitted into the hospital, 6 have died. The town of Zagazig is regarded by the sanitary department of the Egyptian Government as seriously infected and the Caisse de la Dette has granted the plague credit of £20,000, applied for by the sanitary department, which will be drawn from the general reserve fund. According to the investigations made by Major Garner, says Dr. Pinching Bey, head of the sanitary department, in a note to the minister of the interior recently, it would seem that some time before the discovery of the first case, several inhabitants of different quarters of the town had noticed rats in a dazed and dying condition. This mortality among the rats was observed for the first time after a heavy shower of rain.

Plague in Manila Decreasing.—Official reports show that plague in Manila is decreasing, and that during the week ending June 15, 1901, there were reported ten cases with five deaths, eight being Chinese and Filipinos.

Obituary.—Dr. George Schmidt, at Milwaukee, Wis., July 18, aged 53 years—Dr. Charles E. Cooper, at San Francisco, Cal., July 21, aged 40 years—Dr. J. R. Caldwell, at Marcus Hook, Pa., July 23—Dr. L. J. King, at Santa Rosa, Cal., July 22, aged 62 years—Dr. Lawrence Wolff, at Philadelphia, Pa., July, aged 56 years—Dr. I. E. Ross, at Dorrancetown, Pa., July 23—Dr. William A. Watson, at Newport, R. I., July 27, aged 77 years—Dr. M. A. Arnholt, at Pittsburg, Pa., July 25—Dr. Edwin S. Lemoine, at St. Louis, Mo., July 21—Dr. Franklin K. Paddock, at Pittsfield, Mass., July 26.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended July 27, 1901.

Changes in the Medical Corps of the Navy, Week Ended July 27, 1901.

ASSISTANT SURGEON E. O. HUNTINGTON, detached from the Newark, when placed out of commission, and ordered home to wait orders—July 19.

SURGEON C. F. STOKES, ordered to the Oregon, immediately—July 20.

SURGEON P. LEACH, detached from the Oregon, upon reporting of relief, and ordered home to wait orders—July 20.

P. A. SURGEON A. FARENHOLT, detached from the Oregon, and ordered home to wait orders—July 20.

SURGEON G. T. SMITH, detached from the Mayflower, when put out of commission, and ordered home to wait orders—July 24.

P. A. SURGEON D. N. CARPENTER, detached from the Naval Hospital, Chelsea, Mass., and ordered to the Franklin—July 24.

ASSISTANT SURGEON R. R. RICHARDSON, detached from the Naval Hospital, Newport, R. I., and ordered to the Naval Hospital, Chelsea, Mass.—July 24.

ASSISTANT SURGEON J. R. WHITING, resignation accepted to take effect from August 3, 1901—July 24.

Plague in the United States as reported to the Surgeon-General, United States Marine-Hospital Service, from June 28, 1901 to July 19, 1901.

(For reports received from January 1, 1901 to June 28, 1901, see PUBLIC HEALTH REPORTS for June 28, 1901.)

GREAT BRITAIN.

Lord Lister Does Not Agree with Dr. Koch.—It is stated that the *Daily Mail* publishes an interview with Lord Lister in which he said he was absolutely unable to believe the statement of Professor Koch that human beings could not get consumption through drinking the milk of diseased cows, the evidence to the contrary being far too overwhelming.

Koch's Theory to be Investigated.—At the final meeting of the British Congress on Tuberculosis held on July 29, resolutions were adopted favoring the legislation towards suppressing expectoration in public localities. Resolutions were also adopted recommending the notification of cases of tuberculosis and the employment of proper receptacles for the sputum. Furthermore, it has been concluded that these sanitary provisions were indispensable in the crusades against tuberculosis. A resolution was also adopted embodying the opinion of Congress that health authorities should continue their efforts to prevent the spread of tuberculosis through milk and meat, and as the doubts concerning the human immunity from bovine tuberculosis as advanced by Dr. Koch were of the highest interests to the public in general, as well as for agricultural pursuits, the Government should at once institute rigid investigations as to the identity of human and bovine tuberculosis. It was recommended that a permanent national committee be appointed for the purpose of collecting evidence, publishing literature and recommending means for the prevention of this disease.

Mr. Henry Greenway Howse, F.R.C.S., Eng., M.S., and M.B. London, Senior Surgeon, Guy's Hospital, has been elected President, and Mr. Thomas Richard Jessop, F.R.C.S., Eng., J. P., Consulting Surgeon, Leeds General Infirmary, and Mr. F. Howard Marsh, F.R.C.S. Eng., Surgeon to St. Bartholomew's Hospital, have been elected Vice-Presidents of the Royal College of Surgeons of England.

CONTINENTAL EUROPE.

Disagrees with Koch.—Professor Brouardel, dean of the Medical Faculty of Paris, contrary to the recent theory advanced by Dr. Koch, believes that cattle spread tuberculosis. He urges international legislation requiring the notification of the authorities of the existence of tuberculosis, and furthermore urges the disinfection of hotels and public conveyances. He believes that the disease is curable.

Plague at Oporto Denied.—During the past week, according to newspaper reports, official advices received at Madrid positively deny the existence of plague which was rumored to have appeared at Oporto.

Italian Congress of Pediatrics. The fourth congress of pediatrics will convene at Florence, October 15 to 20.

The Utilization of Rejected Diseased Meat.—The Veterinary Society of Moscow is advocating the German plan of dividing the meat in the market into 3 groups: (1) Very good quantity, (2) inferior quality, and (3) bad. The first is sold in a raw state, the second is obtained from animals which suffered from tuberculosis, trichinosis, actinomycosis, inflammation of the lungs and other diseases. This is sold only in the cooked state. The third is obtained from animals which suffered from anthrax and septicemia. This is either destroyed or boiled under pressure of 1½ to 2 atmospheres and sold at the Freibank at a very low price. Thus thousands of dollars are saved, while the poor can get at a low cost meat which has been rendered wholesome by thorough cooking.

Spurious Pregnancy in a Queen.—Professors Snegireff and Gubareff were called to attend the confinement of the queen of Servia. It was found, however, that the royal personage had a spurious pregnancy. The professors departed laden with signs of honor.

Scalded to Death.—In the insane department of the hospital of the government of Kharkoff an insane woman was given a hot bath. The nurse failed to ascertain the temperature of the water, which was boiling hot, and the woman was scalded to death.

Dr. Lindeman, privat docent of the University of Moscow, was elected to the chair of general pathology at the Medical Faculty of Kiöff.

10. Experimental Malaria, Recurrence After Nine Months. P. THURBURN MANSON.

7.—T. Clifford Albutt presents a note upon infection by the urine in convalescence from typhoid fever. A charwoman who had recently recovered from an attack of typhoid fever returned to work upon a farm, and soon afterward an attack of typhoid fever broke out at this place. A short time after this she went to work upon another farm, and typhoid also developed here after her appearance. The woman presented no symptoms of diarrhoea, and Albutt believes that the infected urine was responsible for these outbreaks, and he makes a strong plea for the disinfection of typhoid urine. It has been shown repeatedly that the bacilli are filtered through the kidney in an active state. [T. L. C.]

8.—T. R. Bradshaw presents a further contribution on the evolution of myelopathic albumosuria. A case is mentioned in which albumose was first observed in December, 1899, when the patient, who was then 53 years old, had an attack of mild pneumonia. The quantity was at that time minute, but it had reached a maximum of ten parts per 1,000. Until the middle of May in the present year the patient felt no inconvenience, and was able to follow his profession, but since then he has grown pale and lost flesh and strength. He also found a soft tumor about the size of a hen's egg, in connection with one of his ribs. Bradshaw states that this complete case illustrates two points, one of which is new. First, the presence of albumose in the urine is the earliest symptom of disease, and may be observed for many months before there are any other indications of failing health or any local signs or alterations in the skeleton. Second, the albumose is first excreted in small amounts, but the patient suffers little at this time and is not likely to consult a medical practitioner, and so the urine is not examined until the albumose has risen to a large amount. This early discovery in the memorandum of the case reported was doubtless due to the fact that the onset closely coincided in time with an acute illness, and that the subject of it was a physician. [T. L. C.]

9.—Percy S. Blaker and B. E. G. Bailey report four cases of hemorrhage into the skin and suprarenal capsules. The interesting features of these cases were the sudden onset, rapid course and fatal termination. Not one of the patients was over a year old. The history throws absolutely no light on the causation of the disease; neither does the question of food appear to bear any relation to it. The presence of hemorrhages in the skin and suprarenal capsules would seem to make it more probable that the disease is some form of toxemia. In two cases the blood from the unopened heart was examined bacteriologically with negative results. In its extremely rapid and fatal termination the disease somewhat resembles the epidemic diarrhoea and vomiting of infants. The general condition of the patients was different. They did not present the sunken eyes and the inelastic skin which is frequently met with in the epidemic diarrhoea, and the cyanosis present in these

cases is very rarely, if ever, seen in the skin and suprapubic capsules; the fact that Peyer's patches were much swollen is interesting. The authors believe that these symptoms are the manifestations of a special disease, and that the cause of this disease is a blood poisoning of some form, at present unknown. [T. L. C.]

10.—Dr. P. Thurburn Manson reports the result of a successful experiment of which he was the subject on the production of malarial infection by mosquito bite. As a result of the bite of mosquitoes fed in Rome on a case of benign tertian ague, he developed a double tertian fever. The first symptoms appeared on September 13, 1901, after an incubation period of between ten and sixteen days. The illness lasted from September 13th to September 17th when the presence of the parasite having been fully confirmed, 10 grains of quinine were given. This treatment was followed by 5 grains three times a day for a week, and a subsequent after-treatment of 5 grains three times a day on Sundays for the following three months. There was no recurrence at that time of symptoms of malarial infection after the first dose of quinine, and he kept in normal health until May 30th, 1901, a period of nine months. On this date he began without obvious reason to have symptoms of illness. These were malaise and pain in the splenic region. Two days later a definite malarial paroxysm occurred. This case was one of single benign tertian malaria, the original infection having been the double tertian type.

CONRAD BASAN.

1.—David Wallace speaks of the great difference made in the diagnosis of tumors of the bladder during recent years. The use of the cystoscope in these cases has been of the greatest advantage. Previous to 1888 bladder tumors were considered rare. At the present time, however, they are quite common. This difference is not due to the greater prevalence of bladder growths, but rather to their proper diagnosis. His remarks are confined to primary growths of the bladder wall. Albarran's classification is approved of. Attention is called to the fact that small benign growths may prove fatal, producing, as they do, hemorrhage, cystitis and secondary renal involvement. The most important symptom of bladder tumor is bleeding associated with no pain or other symptom. Occasionally, however, pain and frequent micturition may be present early in the case. The hemorrhage is intermittent, the urine between times being clear. At a later period cystitis develops. Occasionally months, and rarely a year may intervene between the hemorrhages. Tumor cells are rarely found in the urine. The cystoscope is of great value as a diagnostic means. The prognosis depends up-

on the character of the tumor, its extent, site and attachment, and the presence or absence of sepsis. It must be remembered that a tumor with a narrow pedicle may have a deep attachment. This accounts for the occasional recurrence after removal. In operating upon tumors of the bladder the suprapubic route is the one of choice. The vertical incision is as satisfactory as the transverse and is less apt to weaken the abdominal wall. Peterson's bag is not recommended, but the author finds the Trendelenburg position of great advantage. The bleeding after removal usually ceases with the injection of hot water. Where it is possible it would be wise to remove a portion of the whole thickness of the bladder wall. Free access must be had in operations for these tumors, and the urethral or perineal methods are not approved. Drainage by means of Cathcart's adaptation of the Sprengel pump is to be employed after operation. Patients are allowed to sit up within a day or two after operation. The latter part of the author's paper is devoted to the treatment of enlargement of the prostate. The greatest stress is laid upon the necessary asepsis in the employment of the catheter. The varying results following castration and vasectomy are due to the varying pathological conditions of the gland. When the gland is largely composed of erectile tissue the results are most satisfactory. Wallace has never seen a permanent fistula follow a suprapubic prostatectomy when the entire urethral obstruction had been removed. [J. H. G.]

2.—Marsden read a paper before the Manchester Medical Association on the diagnosis and treatment of typhoid fever. The direct diagnosis of typhoid fever may be made either by the physical signs or by specific tests. In regard to the former he states that it depends upon the history of a recent acute illness, the onset being marked by headache, chills, lassitude, epistaxis, splenic enlargements, fever, the appearance of rose spots, absence of leukocytosis, and occasionally by such complications as hemorrhage and intestinal perforations. In regard to the diagnosis by specific tests he believes that the serum reaction may, at times, be as convincing and certain as any imaginable symptom-complex. In a recent series of 200 cases considered by the author, he encountered 12 doubtful reactions. The author thinks that an incomplete serum reaction should be valued about as much as the Ehrlich diazo reaction. By that he means that clinical manifestations should be the guide to the diagnosis. If the blood be examined periodically it is of rare occurrence *not* to obtain the serum reaction in a case of enteric fever, but not infrequently it also occurs in patients suffering from other diseases. He summarizes the diagnostic value of the Widal reaction as follows: At the end of the first week a negative reaction points strongly against the probability of enteric fever, and that each succeeding negative result increases this uncertainty. If a negative reaction is obtained during the convalescence of a disease, the diagnosis of enteric fever should be abandoned, unless the characteristic symptom-complex and physical signs were present during the course of the disease. The diagnosis of enteric fever should always be uncertain during the first week of the illness, unless a well-marked Widal reaction is obtained, or upon the appearance of rose-spots, intestinal hemorrhage, etc. In his own experience he has found that splenic enlargements occur early in the course of the disease. Ehrlich's diazo reaction may be obtained in measles and acute tuberculosis, and he believes that it may also occur in other diseases. For this reason little reliance should be placed upon this test. Special localization of symptoms sometimes gives rise to difficulty in diagnosis, for the symptoms may be those of meningitis, pneumonia, nephritis, and cystitis, until the further development of the disease or the occurrence of the Widal reaction. He emphasizes that clinically the appearance of rose-spots on several consecutive days is the only sign upon which absolute reliance can be placed. In regard to treatment, he maintains that from the earliest possible moment the patient

should be confined to bed. The diet should consist of fluids. Three weeks after the termination of the attack the regular diet may be resumed. During the acute stage of the illness he recommends cold bathing. [F. J. K.]

3.—Ewart reports successful results with the **posture treatment in bronchiectasis and in chronic bronchial affections**. The first case which he reports was one of bronchiectasis which occurred in a girl, 20 years of age, who had been suffering from cough and expectoration, worse during winter, for a number of years. During a violent, painful, orthopneic paroxysm of cough the patient was advised to lie down and the foot of the bed was raised about 14 inches. While she remained under treatment the bed was permanently raised. Improvement immediately followed the elevation of the foot of the bed. The second case was one of bronchitis with violent cough and profuse expectoration, which occurred in a woman 30 years of age. The patient complained of orthopnea, especially during fits of coughing. Immediately after elevation of the foot of the bed the symptoms subsided. The subsequent treatment consisted of elevating the foot of the bed for an hour, two or three times daily, and in the administration of ichthyol. The patient improved rapidly. [F. J. K.]

4.—E. Stanmore Bishop describes an interesting growth of the **gall bladder** which he believes to be unreported to in surgical literature. The growth was of cystic formation and involved the whole of the gall-bladder. Its microscope examination showed that there had been a simple hypertrophy of the mucous lining of the wall with an immense development and extension of the glandular layer. No inflammatory changes are observable, and the author is at loss to account for the condition. [J. H. G.]

5.—Perigal reports a case of **meningitis** which was probably of **influenzal origin**. The patient was 24 years of age. He appeared to be suffering from a severe attack of influenza which began very suddenly. At the time of his illness influenza was prevalent. Well-defined symptoms of meningitis developed, the patient dying of that disease. At the post-mortem examination well-defined anatomical lesions of meningitis were found. [F. J. K.]

6. Buchanan reports **three unusual cases of cerebro-spinal fever**. The first case occurred in a male, 40 years of age. This case was of peculiar interest as it was complicated with arthritis involving both knees, both ankles, and the right wrist. Death occurred on the sixth day. The autopsy presented well-defined signs of meningitis; the joints were swollen, and the serous cavities of the joints were filled with a flaky, yellow, oily fluid. The second case of cerebro-spinal fever occurred in a male 55 years of age. This case was of interest as it was complicated with hemiplegia. At the autopsy a thick fibrinous exudate was found over the upper surface of both hemispheres of the brain. The brain did not reveal a hemorrhage in any part. The third case occurred in a man, 45 years of age, and was an example of the fulminant hemorrhagic type of cerebro-spinal fever. The diagnosis was confirmed by autopsy. [F. J. K.]

7. Corliss and Cropper relate a case of **renal colic** in which none of the characteristic symptoms were present, and the diagnosis only made by the passage of sharp fragments of the stone. [J. H. G.]

8.—Hallowes has met with four cases of **eclampsia** in somewhat over two thousand labors, all of which terminated favorably under rectal injections of chloral hydrate. All four cases were primiparae; two commenced antepartum and two postpartum; one antepartum and one postpartum were illiterate. In all four cases the convulsions were severe and of fairly frequent occurrence. Blood-letting to the extent of 20 oz. was tried in one case, postpartum, but without effect. On the continuance of the convulsions, 60 grs. of chloral hydrate were injected per rectum in one ounce of water. This was repeated on the slightest recurrence of twitching. In another case after the administration of chloroform the convulsions recurred in about

an hour and immediately 60 grs. of chloral were administered per rectum. Injection was repeated three times at intervals of three to four hours. All the cases were at full term. [W. A. N. D.]

9.—J. D. Malcolm describes a case of a woman, 45 years of age, from whose abdomen large quantities of clear fluid had been withdrawn at different times during the previous 18 months. After one of these tapplings the author was enabled to palpate a firm hard mass which appeared to rise out of the pelvis. This was thought to be a malignant growth. Later, when the abdomen was opened this mass appeared to be a cyst, but upon careful examination it proved to be a large mass of adherent intestine. Malcolm says that the appearance and feel of this mass was so like that of a cyst that one might have been tempted to introduce a trocar. He refers to a similar case in which this unfortunate procedure was resorted to. The absence of the intestine above the supposed growth, and resonance upon percussion, are two points which will enable the surgeon to arrive at its true nature. [J. H. G.]

10.—Basan gives a report upon 40 consecutive cases of **intubation of the larynx in diphtheria**. In his experience he found the operation a very easy one to perform. Out of 32 cases in which intubation alone was performed, 28 recovered and four died. Out of 8 cases in which intubation was subsequently followed by tracheotomy, 5 recovered and 3 died. He concludes the article with a report of a number of complicated cases. [F. J. K.]

MEDICAL RECORD.

July 27, 1901.

1. Inebriety. CHARLES L. DANA.
2. Primary Resection of the Intestine for Gangrenous Hernia; Report of Two Cases of Successful Joining by Lateral-Anastomosis, with the Connell Suture. THOMAS H. MANLEY.
3. The Use of Sulphate of Copper in Affections of the Cornea and in Affections of the Lid Other than Trachoma. HERBERT CLAIBORNE.
4. Needed Reforms in the Management of Youthful and Insane Criminals. WILLIAM GLASSELL SOMMERVILLE.

1.—Charles L. Dana studies the causes, duration, prophylaxis and management of inebriety. Among 350 patients he found that drinking habits existed in one or both parents in all but ten. The father was usually the drinker. In another series of 210 cases the percentage was much lower; 25% gave a negative hereditary history. It is not the day laborers, but the mechanics, artisans, and small tradesmen that furnish the greatest proportion of cases. The indoor workman is oftentimes the victim. About one-third of the inebriates are women. Among 30 periodical inebriates, two-thirds began drinking before 20 and all began before 30. Studying the capacity of men for getting drunk, it was found that it was rare to find a man who had been drunk over a thousand times and that two thousand was the maximum in any ordinary inebriate experience. Dana believes that the agencies for preventing and lessening the injury done by alcohol must consist in: 1. Teaching. 2. Control of the sale, making it impossible to secure impure alcohol and difficult to secure even good alcohol, and especially difficult for those whom it is a poison. 3. Avoidance of transmission of degeneration through the marriage of alcoholics. 4. Personal supervision of those who become inebriates. The treatment of all that class known as inebriates is at present of two kinds, the ideal and practical. The ideal treatment is the supervision of the case in an institution, ensuring absolute abstinence from alcohol, in all forms for at least one year, and personal supervision and watchfulness for two years longer. The practical treatment, however, consists in the use of strychnine, atrophine and apomorphine, with these are combined tonics, laxatives, full feeding and physical instruments exercised

on the patient by the persistence of the treatment. Then he suggests that the patient who wishes to undergo treatment, should stop drinking and usually smoking, and take for three weeks a mixture of nux vomica, capsicum, and cinchona. The maximum dose should be continued for a week and then reduced as it was increased. One teaspoonful three times a day, increased by 20 drops daily to half an ounce three times a day. At the same time two drachms of bromide of sodium should be given in cases of nervous irritability and insomnia. The patient should be fed well and very often, and should avoid getting tired or hungry. After two weeks rest from medicine, the course should be repeated. After the second course, a month's interval can be allowed, and repeated again and so on until the end of the year. [T. L. C.]

3.—J. Herbert Clahorne presents a paper on the use of sulphate of copper in affections of the cornea and in affections of the lid other than trachoma. Copper sulphate in the form of the solid stick is indicated in all acute attacks of inflammation of the cornea in which there is a thickening with a succulent velvety appearance of the upper lid; in all recurrent attacks of superficial keratitis in which the same condition of the upper lid prevails; in infiltrations of the cornea which are the results of preceding inflammations, associated with the same condition of the upper lid; in maculae of the cornea in children and adults which have occurred a reasonable time after an inflammation, whether the upper lid presents a characteristic appearance or not; in chronic conjunctivitis attended by thickening of the lid associated with blepharitis; in chronic dacryocystitis particularly in those cases in which the canaliculus has been slit attended by chronic conjunctivitis. [T. L. C.]

4.—W. G. Sommerville discusses **needed reforms in the management of youthful and insane criminals**. He believes that it is detrimental financially as well as socially and morally to release prisoners when there is a probability of them returning to crime. The determinate sentence permits many prisoners to be released, who are morally certain to return to crime. The indeterminate sentence is the best method of affording the prisoner an opportunity to reform. The ground for the imprisonment of the criminal is, that he is dangerous to society. (These are MacDonald's views.) [T. L. C.]

MEDICAL NEWS.

July 27, 1901. (Vol. LXXIX, No. 4.)

1. An Improved Method of Treating High-seated Cancers of the Rectum. ROBERT F. WEIR.
2. A Case of Embolism of One of the Right Lenticulo-Optic Arteries Complicating Pneumonia, with Autopsy. CHARLES J. ALDRICH.
3. An Attempted Investigation of Some Christian Science "Cures." LAWRENCE IRWELL.
4. A Nasal Condition Affecting the Ocular Muscles. HEBER NELSON HOOPLÉ.
5. Criminals and Defectives: How Best to Reduce their Numbers. J. C. McCASSEY.

1.—R. F. Weir's method for treating **High Seated Cancers of the Rectum** is as follows: After opening up the abdomen he takes the finger and freely detaches the divided peritoneum so that the bowel and entire contents of the sacral curve are liberated behind nearly to the tip of the coccyx and in front to the edge of the prostate. This gives room to tie around the bowel some three inches from the anus a couple of iodoform tapes about an inch apart. The intestine is then cut through and being free is readily raised out of the abdominal wound. The lower end of the rectum is then seized by forceps and is drawn down and out of the anus in an everted condition. Untying the tape that closed this everted bowel, its lumen is opened so that a long pair of forceps could be carried through it up into the pelvis, when the end of the upper bowel is brought down

within its clasp and by it the latter is drawn through the lower bowel out. A couple of needles passed through the invaginated ends of the bowels, near their margins, allows easy union by sutures of their edges with their knots inside the bowel, so that the pelvis and general abdominal cavity is separated from one another by the peritoneal shelf. He deems it best to provide drainage from the peritoneal space below by a tube introduced just in front of the coccyx. [T. M. T.]

2.—C. J. Aldrich reports a case of the above condition, and reviews the literature of **cerebral embolism complicating pneumonia**: (1) Da Costa has reported six cases of phlegmasia alba dolens in pneumonia; (2) Anders states that the venous thrombosis is seldom seen and embolism of the large arteries is a rare complication. He also states that the cerebral embolism causing aphasia, and even hemiplegia, has rarely been observed; (3) Loomis says a very rare occurrence is partial paralysis of the muscles which are involved during the convulsive period; such paralysis is often permanent; (4) Osler thinks that embolism of one of the larger arteries is a rare complication. He has seen embolism of the femoral artery at the height of pneumonia. Transient aphasia has been met with in a few instances, setting in abruptly with or without hemiplegia. [T. M. T.]

4.—H. N. Hoople states that **asthenopia of the ciliary and external ocular muscles** is due to pressure in a limited area of the nose. The pressure is chiefly confined to the middle turbinate, but it may extend to the ethmoid cells, especially in cases of great hypertrophy of the middle turbinate. The author wishes to emphasize that without hypertrophy where the middle turbinate is tightly compressed against the septum, or the septum is deflected against the middle turbinate, or the middle turbinate is crowded by a deflected septum against the ethmoid cells, in all these instances we may have, and are almost certain to have sooner or later, muscular asthenopia. [T. M. T.]

5.—J. C. McCassey advises the following remedies for **Diminishing the Number of Criminals and Defectives**: (1) It is more economical to put forth every effort to prevent the formation of bad habits in the young than to try to reform confirmed transgressors; (2) The average length of sentences, including life sentences, is only two years, while the average confinement in insane asylums is four years; (3) The board of pardons should consist of sentencing judges, the warden of the prison, and one of the chief justices of the State. This board should meet quarterly, hear evidence and correct mistakes of sentence; (4) The issuing of marriage licenses should be restricted by a national law requiring medical and other certificates to be filed with the Probate Court, showing that the applicants for marriage licenses are free from insanity, criminality and other hereditary taints. For the cure of the social evil the following prescription is offered: Extension of manual education and industrial schools; improvement in motherhood; stop lease system; extension of reformatory plan; adopt intermediate sentence; improvement in jails; extension of probation system, both for youths and adults, as in Massachusetts; work for prisoners even on short sentences and allowing them a portion of their earnings to be sent to their homes or families. Abolition of spoils system in prison management; higher grade of prison officers; physicians should be wardens of penitentiaries and executive officers of reformatories. [T. M. T.]

THE NEW YORK MEDICAL JOURNAL.

July 27, 1901. (Vol. LXXIV, No. 4.)

1. The Wesley M. Carpenter Lecture on Conjugation in the Asexual Cycle of the Tertian Malarial Parasite. JAMES EWING.
2. Some of the Conditions Following the Bottini Operation for Prostatic Obstruction. L. BOLTON BANGS.

3. Mental Disturbances in the Course of Cardiac Disease.
A. ZEDERBAUM.
4. The Ophthalmoscopic Examination for Kilday Disease.
EDWARD JACKSON.

1.—J. Ewing, in *Conjugation of the Asexual Cycle of the Tertian Malarial Parasite*, gives the following development: The malarial parasite may be said to begin its existence, in the human host, by a series of generations of amoeboid bodies produced after conjugation of partially differentiated individuals. After the capacities of this method of reproduction have been exhausted, the sexes become separated, the male forms represented by the flagellating bodies, merozoogametes, and the female by the large, pale, hyaline, non-flagellating bodies (macrogametes). These forms are sterile for the human host, but in the mosquito fertilization of the macrogamete by the flagellum or merozoogamete takes place, and the resulting motile form, the zygote, penetrates the tissues of the mosquito and becomes encysted. From this cyst develop the germinal rods which are inoculated into the human host through the salivary glands of the mosquito, to begin anew the pyrogenous or amoeboid cycle. At several points in the series there remain wide gaps in our knowledge. We do not yet know how the germinal rods are transformed into amoeboid bodies. The development of the sexual forms of the tertian parasite can at present only be offered as a probability, not as demonstrated fact, while the origin of the aestivo-autumnal crescents is as yet entirely obscure. At the other end of the series there is possibly an entire new phase of development of the parasite or the production of some "resistant body" in the external world apart from either man or mosquito. [T. M. T.]

2.—L. B. Bangs believes that the spontaneous urination which follows the operation is due, not only to the formation of the grooves, but to contraction of cicatrices and to atrophy of the gland tissue, for the following reasons: (1) Improvement in freedom of urination progresses, so that some of the patients among the number in which improvement only was reported are now able to empty the bladder. This fact, he states, gives him hope of the permanency of results; (2) In two persons he was obliged to open the bladder above the pubes; one, two years, and the other, one year after the Bottini operation, for the removal of stone from diverticula. In each of these cases there had been a shortening of the urethra and a vast improvement of the facility with which instruments could be passed into the bladder, and in one of them there had been such steady improvement in urination that even during the symptoms of a stone it was found that the catheter was needed only for purposes of treatment. At the time of the lithotomy the grooves could be distinctly felt, and the reduction in the size of the intravesical portion of the prostate, which had been ascertained by the searcher, could be verified by sight and touch; (3) A specimen which was removed from a patient who died suddenly from a cerebral clot three months after the operation, who had been entirely dependent upon his catheter, no spontaneous urination having taken place for a year, and who immediately after the operation resumed normal urination and never used his catheter again, shows the atrophy which has taken place in the intravesical portion where the incisions were made by the Bottini operation, whereas the *extravesical* portion shows no change; (4) Two of the author's patients reported to him a few weeks after the operation that, although coitus was possible, there was no ejaculation, which certified to him that the contraction has been sufficient to occlude the ducts, for in neither of these cases was the incision carried so far forward as to affect the veru montanum. [T. M. T.]

3.—A. Zederbaum, in *Mental Disturbances in the Course of Cardiac Disease*, concludes as follows: (1) That the heart in a number of women during pregnancy and puerperium is subject to hypertrophy, which may become permanent and pathologically affect the valves; (2) That

latent cardiac disease of rheumatic and other origin may first come to the front during pregnancy or in and after labor. [T. M. T.]

4.—E. Jackson, in the *Examination of the Eyes for Kidney Disease*, gives as the most constant symptom alteration of the retinal veins. These are dilated and tortuous, especially some of the parts of the small veins which arise about the macula. Other parts of a vein may be hidden in a swollen, hazy retina, so that the dilated part may look unlike a vessel, but like a hemorrhage. Next, hemorrhage may be found anywhere in the retina; it may even extend into the vitreous. The dark red spots that indicate it may be large or small, many or few, or, at times, even quite absent. Swelling and opacity of the retina are usually confined to isolated patches, or to the region surrounding the optic nerve. The color of the patch may vary from a dirty-red to a snow-white, or a gray-blue. The swelling is to be measured by the refraction of its summit. Sometimes it looks like a small detachment of the retina. But actual detachment may also occur. White spots arise from fatty degeneration. These are regarded as most characteristic when arranged in rows, radiating from the center of the macula. Large spots are confined to this part of the fundus or to the neighborhood of the optic disc, but small ones may be scattered in all parts of the eye-ground. White streaks are occasionally seen along the arteries or may wholly replace them. The optic nerve is often reddened and opaque. It may be swollen until it exactly resembles the choked disk of brain disease. [T. M. T.]

2.—W. A. Wells presents a paper on the after-treatment of operation on the nasal accessory sinuses. He states that persistence of suppuration after operation is generally due to one or several of the following causes: 1. Syphilis or tuberculosis in the patient; incompleteness of the operation; presence of polyp or other obstructive condition in the nose; an empyema in a neighboring sinus; inadequacy of the local treatment. 2. The after-treatment requires that not merely the antiseptic applications to the sinus, but that the patient's general state of health, must be investigated, and a careful supervision constantly maintained over the condition of the nasal fossa. The latter must be kept free from secretions, and polyp and other obstructing conditions removed whenever found. 3. Empyema in a neighboring sinus, whose ostium is in close relation with the sinus operated on, will maintain the suppuration in the latter, unless cured. The frontal is frequently the cause of antrum disease, and the ethmoid the cause or the effect of disease of both the antrum and the frontal sinus. 4. The cause for the continuance of the suppuration is attributed in many cases to the fact that all diseased tissue was not removed at the time of the operation. The irregularities and anomalies in the form of the sinus are often responsible for the failure to have reached every point where disease was located. In such cases curettage of the sinus must be repeated from time to time according to the indications. 5. The institution of the proper local

after-treatment is a matter of extreme importance. The so-called dry treatment is insufficient and unscientific, because it does not provide for the removal of the products of suppuration; only a mass of powder is superadded to a mass of decomposing debris, whereby an absorbable accumulation results, which may retard recovery and give rise to unpleasant symptoms. 6. Frequent and thorough irrigations constitute the most rational method of treatment. Protargol in 2 to 5% solution has given the most favorable results, especially when alternated with a thorough swabbing of all parts of the inner wall of the sinus with a 20 to 40% solution in water and glycerine. 7. Immediately after operation the sinus should be packed with iodoform gauze, which remains in place for thirty-six to forty-eight hours. Subsequently the sinus is irrigated daily, and later on every other day. A thorough rubbing of the walls of the sinus is made with the solution mentioned every three, four or five days, according to individual requirements. [T. L. C.]

3.—D. N. Blakely and F. G. Burrows discuss diphtheria as a complication of measles. During the period of two and one-half years from February 1, 1898 to July 31, 1900, there were treated at the South Department of the Boston City hospital 150 patients who had measles and diphtheria. Of these, 34% died. The death rate in uncomplicated diphtheria patients for practically this same period was less than 13%. Of the whole number, 82, or 52%, had laryngeal diphtheria, and of these, 36, or 44%, died. In the 82 laryngeal cases there were 47 intubations, with a death-rate of 55%; in the remaining 35 in which intubation was not practiced, the death-rate was 29%. The earlier in the course of measles that diphtheria develops the more serious is the prognosis. These authors believe that the existence of diphtheria or the possibility of its onset should be considered in every case of measles; for the congestion of the mucous membrane and air passages caused by the measles renders it especially fertile for the growth of the organism of diphtheria. [T. L. C.]

4.—J. C. Hubbard reports very satisfactory results from the treatment of umbilical hernia by strapping. This treatment must be persisted in. The younger the child the earlier the cure is to be expected. The fear of recurrence or failure is slight. [T. L. C.]

1.—E. Fletcher Ingals discusses first, the various anatomical variations and the pathological characteristics of the frontal sinus. The most frequent cause of empyema of the sinus is acute coryza. Infection of the sinus usually follows that of the other sinuses. Chronic empyema

usually results from an acute inflammation of the sinus and is the result of interference with free drainage. Symptoms of the condition usually come on a week or two after the subsidence of the coryza. They are: Photophobia, pain in the eye and supraorbital region, together with free lacrymation. Pain is usually intermittent until the eighth or tenth day, when it becomes constant. Severe symptoms subside with the discharge of pus. In latent empyema, symptoms come on insiduously, the first to be noticed being pain in the supraorbital region, which is not infrequently treated as syphilitic headache. These cases may go on for years undiagnosed. When there is an obstruction to the discharge the condition is manifested by external signs, such as swelling, edema and so forth. Transillumination should always be employed, but is of doubtful value. The use of the probe or canula is of value, but is not without danger. Since tumors of the sinus may be attended by purulent discharge the differential diagnosis is impossible unless the cavity is open. When the sphenoidal sinuses are involved the pain is severe, and usually there is early blindness, whereas in empyema of the frontal sinus, the inflammation will involve the anterior part of the orbit with less serious consequences to the eye. The prognosis of the acute condition is good, but of the more latent cases less favorable. Treatment in acute cases consists in the use of warm soothing detergent and antiseptic sprays. The application of the watery extract of the adrenal glands or the guarded use of cocaine may be employed to keep down the swelling and allow free drainage. These measures failing, it becomes necessary to thoroughly irrigate the frontal sinus and establish free drainage. This may be done through the nose with Palmer's drill or Krause's trocar. The most satisfactory treatment, however, consists in opening the sinus externally and establishing free drainage into the nose. The external opening should be maintained in the majority of cases until all discharge ceases.

[J. H. G.]

2.—R. W. Payne speaks of the difficulties attending the treatment of chronic suppurative inflammation of the frontal sinus. Most of these cases drain rather freely into the nose, producing little disturbance excepting that which accompanies the discharge and the development of polypi. The author makes a strong plea for a thorough opening of the sinus with the removal of all disease from every recess. Attempts to treat these cases through the infundibulum he considers dangerous and unsurgical. It is the author's custom to leave bony bridges across the sinus to support the skin. The cavity is drained externally at its two extremities for five or six days. [J. H. G.]

3.—Farrell contends that asthma is often due to nasal defects, such as a deviated septum, hypertrophied turbinate, septal spur, and polypi. Permanent cure occurs in the majority of cases after operation. The author suggests nothing new in the matter of technique. He employs the spore, the curette, the knife and the saw, but never the galvano-cautery in nasal work. He gives a report of two cases of asthma due to nasal defects, which recovered after operation. [F. J. K.]

4.—Richards reports an unusual anomaly of the faucial tonsil, which occurred in a woman, 60 years of age. She stated that her throat had been paining her for two years, and there was also a sense of discomfort in that region. Upon examination the right tonsil was found to be enlarged. Upon attempting to remove this hypertrophied mass with the tonsillotome, he was unable to cut through it; an examination was then made, and he could distinctly palpate a bony mass. With a stout bone-cutting forceps the mass was removed. The bony substance within the tonsil proved to be a portion of the styloid process. On the left side he also detected the tip of the styloid process.

[F. J. K.]

5.—Cobb discusses the effects produced upon the general health by the so-called catarrhal diseases of the nose and throat, and come to the following conclusions: (1) The general health is affected through diseases of the nose and throat, either by obstructed nasal respiration or by extension of diseases of bacterial origin; (2) The general health is affected by diseases of bacterial origin either by surface extension, extension into deeper tissues, or by the migration of bacteria to distant parts of the body, by swallowing

the exudations which contain bacteria and by absorption of toxins; (3) Bacteria are carried to distant parts of the body either by the lymph or by the blood; (4) Septic infection due to diseases of the throat and nose are similar to infection from other sources; (5) Much of the indigestion from which these patients complain is due to, or exaggerated by the swallowing of the discharges from the throat or nose; (6) A purulent collection in the nasal chambers or accessory sinuses may give rise to chronic sepsis. [F. J. K.]

6.—Mitchell discusses the changes in the facial bones due to adenoids, and contends that an alteration in the development of the superior and inferior maxillaries, palates, vomers, turbinates, ethmoid and sphenoid bones occurs in mouth breathers. There is also a displacement of the front teeth and a prominence of the alveolar processes in these individuals. He emphasizes the necessity of recognizing any evidence of previously existing adenoids, so as to locate sources of ear and throat disturbances. [F. J. K.]

7.—E. B. Dench says that it is a question whether the mastoid is not involved to some extent in every case of acute middle ear disease. This does not mean, however, that surgical interference is indicated in every case. In speaking of the symptoms he says that local tenderness is a most important sign and present in almost every case. The point of maximum tenderness is usually over the antrum. Temperature is of value from a diagnostic point of view in children, but is often entirely absent in adults. Both a profuse discharge and a diminution of discharge are indicative of mastoid involvement. The occurrence of facial paralysis is of no diagnostic value. Any bulging of the upper portion of the tympanic membrane in cases of middle ear suppuration should be looked upon with suspicion. As soon as there is the slightest indication of mastoid disease the patient should be kept absolutely quiet and the bowels freely opened. In addition to this a free incision should be made through the drum membrane. The value of local depletion is underestimated. The author does not favor, however, the abstraction of blood from the external mastoid surface. The application of cold is not applicable to all cases, and should never be kept up longer than 48 hours. It is very apt to mask the symptoms. When once employed it should be employed continuously, and not intermittently. In doubtful cases the author advocates exploratory operation. The author has operated upon 316 mastoid cases with but 14 deaths, and none of these were due to the operation itself. [J. H. G.]

8.—J. W. Boyce discusses at some length the various methods of anastomosis of the ureter, and reports a case in which he resected one inch of the ureter and then performed a successful end-to-end anastomosis. Twelve such operations have been performed with two deaths, neither of which could be attributed to the operation. Reference is made to a patient in whom the author performed an oblique end-to-end anastomosis five years previously, and who at present is in perfect health. There have been 22 cases reported in which the severed urether has been united and in which there followed no urethral incompetency. The author recommends the end-to-end anastomosis. [J. H. G.]

9.—Stern believes that uremia is due to a disturbance of osmotic tension. He maintains that when the excretory activity of the kidneys is interfered with, the blood plasma becomes concentrated and by exerting a high degree of osmotic tension, other body fluids also become inspissated. This high degree of inspissation of the body fluids, which is followed by the symptom-complex called uremia, he has termed mechanical intoxication. Reference is made to the work of Lindermann, who showed that the phenomena of uremia may be brought about by the injection of large amounts of salt solutions into the blood. [F. J. K.]

10.—Koch delivered an address on "The fight against tuberculosis in the light of the experience gained in successful combat with other infectious diseases," before the general meeting of the British Congress on Tuberculosis held in London, July 23, 1901. This author classes tuberculosis in the list of preventable diseases such as plague, cholera and typhus. He believes that the sputum from tuberculous subjects is the main source of infection in human tuberculosis. In this address Koch states that

he feels justified in advancing the view that human tuberculosis differs from bovine tuberculosis, and cannot be transmitted to cattle. He performed a number of experiments on young cattle in order to demonstrate that these animals would not contract human tuberculosis. The animals were inoculated with tubercle bacilli, taken from cases of human tuberculosis, in various ways. All of the animals were absolutely insusceptible to infection by the bacilli obtained from cases of human tuberculosis. Koch further emphasizes that man is probably not susceptible to bovine tuberculosis, and therefore does not deem it necessary that any measures should be taken against the extermination of bovine tuberculosis. In view of the theory that the danger of its being transmitted to man is, at the most, very slight. In this address he also dwells upon the importance of establishing hospitals and sanatoria for consumptives, and urges the adoption of obligatory notification. He also emphasizes the great importance to be gained by educating the public in regard to the infectiousness of tuberculosis and the best way of protecting oneself. [F. J. K.]

5. Lithemic or Recurrent Coryza. B. K. RACHFORD.
6. Early Stages of Extrauterine Pregnancy. E. H. TROWBRIDGE.
7. Inflammation of the Sigmoid and Colon. R. D. MASON.

1.—J. G. Adami contributes a paper on the classification of intoxication from a pathologic standpoint. He mentions the terms "exogenous intoxication" and "endogenous intoxication" as introduced by von Jaksch and observes the caution which should be exercised in the employment of these two terms. Especially should the terms poison and intoxication be clearly differentiated. Adami then goes on to show the confusion which is apt to arise by adopting this classification. Especially objectionable is the term auto-intoxication, which he would define as follows: An auto-intoxication is an intoxication set up by the action of substances formed by or from the cells of the body; that is to say, either by the secretion of these cells, or by the products of disintegration. Such auto-intoxication is endogenous when the poison so formed acts without any preliminary passage out of the system; is exogenous when it is due to reabsorption of the secretions. Adami would suggest the following classification of the intoxications: 1. Exogenous, due to the actions of poisons entering the system from without. I. Exotic or introduced, due to the action of substances foreign to the organism, which gain entrance through the skin, the digestive, the respiratory or the genito-urinary tract. II. Indigenous or excretory. (a) Indirect intoxication, due to the absorption of retained excreta. (b) Disintegrative, due to the absorption of decomposition and fermentation products developed in the external secretions through the action of those secretions. 2. Endogenous. 1. Direct intoxication. (a) Internal secretory, due to the action of excessive or unneutralized or modified discharges from the cells of one or other tissue acting directly upon the other tissues of the body without previous discharge from the system. (b) Disintegrative, due to the action of the products of decomposition and necrosis of one or other tissues acting in a similar manner. II. Parasitic. (a) Microparasitic, the infections. (b) Macroparasitic. [T. L. C.]

2.—Charles E. Woodruff presents a paper on maternal impressions and states that they do not cause the stigmata of degeneration. He believes that none of the other false popular beliefs causes so much worry and distress, nor leads to such absurd conduct on the part of pregnant women, and that much practical good will come from every attack upon this absurd idea. This article contains many references from the literature of the subject which are of general interest. [T. L. C.]

3.—L. M. Loch reports two cases of **emphysematous gangrene caused by the bacillus aerogenes capsulatus**. The second case is peculiar in the absence of the usual traumatic history, and the fact that the patient survived with a useful, although mutilated extremity. [T. L. C.]

4.—Joseph Ransohoff reports a case of **cystadenoma of the pancreas with extirpation**. The patient recovered and left the hospital four weeks after the operation. [T. L. C.]

5.—B. K. Rachford reports a case of **lithemic or recurrent coryza** which condition is sudden in onset, and is characterized by intense photophobia and an irritating hypersecretion from the eyes and nose. The patient is in a state of extreme nervous irritability. The condition disappears within a few days. The exact nature of the coryza was determined in the case reported, by the fact that the urine passed during the attack was scanty, high-colored, strongly acid in reaction with a specific gravity of 1.030, and contained an excess of the alloxuric bodies. [T. L. C.]

17.—**Gangrene of the extremity** is the natural consequence of occlusion of the main artery of the extremity. In this article Bunge discusses the **pathological anatomy** only. From a thorough review of the literature, Bunge concludes that the majority of investigators believe that the mass of cells, pigment, and blood-vessels found in the occluded artery with gangrene, is a product of a primary growth of the intima; while a few observers consider this mass an organized thrombus formed by sclerotic change in the arterial walls. In senile gangrene there is a primary sclerotic or atheromatous thickening in the walls of the artery, with secondary thrombosis. Bunge gives in detail, with excellent histological illustrations, the histories of 15 cases from von Eiselberg's practice. Five were senile gangrene, 5 spontaneous, and 5 diabetic. In all cases the lower extremities were affected. From the full descriptions of the histological conditions found, he states that the **pathological product in the intima is sclerotic**. In one case the increase in the intima was due plainly to growth both of the interlamellar and intermediate layers of the intima. Bunge found no thinning of the media, which he believes occurs only secondarily. Elastic fibers are found in sclerosis, with a tendency to increase excessively. In the larger arteries **obliterating endarteritis** occurs. He concludes that diffuse, or oftener circumscribed arterio-sclerotic thickening of the intima, multiple stenosis (rarely solitary), occur in the lumen of the vessel, in one or more of the main arteries of the extremity. These changes may cause occlusion of the vessel. As these changes occur near the branching off of smaller vessels, it is difficult for a collateral circulation to become established. **Thrombosis takes place behind this sclerosis**, completely occluding the vessel. In one case syphilis was the predisposing cause.

[M. O.]

18.—During five years, Rosenstein has collected 192 malignant tumors of the breast which were operated upon by von Eiselberg. One hundred and seventy-six were carcinoma (14 being for recurrence), and 9 sarcoma. The

other six were benign tumors thought to be cancer. Only 135 of the cancer cases were primary. The average age was from 40 to 60, most frequent from 50 to 60. Cancer appears, on an average, 5 years after the menopause. Eighty-five per cent. occurred in married women who had borne children. They came under observation about 10 months after the tumor first became noticeable. The tumor was generally adherent to the skin, muscles, etc., and the axillary glands were involved by that time. Ulceration was also frequently observed. The supra-clavicular glands were affected in 13% of the cases of carcinoma; metastases occurred in 13 cases. Over half of the tumors affected the left breast, most often situated in the middle or the upper outer quadrant of the breast. Eight of the 9 cases of sarcoma were primary. The average age was 41 years. Seven were in unmarried women. These tumors came under treatment about 5 months after they had first been noticed. Adhesions were also noted earlier than in cancer. The axillary glands were enlarged in 5 cases; ulceration occurred in 4. Metastases existed in 2 cases, both of which were inoperable. Five tumors were much larger than the carcinoma. In earlier years, the breast was amputated and the axilla cleared of all lymphatic tissue. Later the pectoral fascia and the greater pectoral muscle were removed. Now the lesser pectoral muscle is also removed. Chloroform is used as the anesthetic. The breast was amputated 145 times, and 30 more operations followed for recurrence. The axilla was cleaned out in every case; the pectoral fascia in 104 cases; the greater pectoral muscle in 68; the lesser in 39; the clavicular lymph-glands in 17; and several ribs in one case. Thirty-two tumors had ulcerated, 7 of which were infected. Three other cases of infection occurred, a total of 10 out of 175 operations. Some fever was seen in 21 cases after operation. Only three cases died after operation. Out of 186 cases, 175 operations were performed. Seventeen were not cured, as three died, three refused operation, and 10 were inoperable. Of the rest only 107 have been heard from lately. Forty-four of them have died, 25 with recurrence. Sixty-three are still living, 54 of them perfectly well. Weakness and swelling of the arm upon the side operated seems more frequent now than it was formerly, when the less radical operation was performed.

[M. O.]

19.—Von Eiselberg saw 75 cases of **cancer of the rectum** during the past five years, 44 of which were in men, 31 in women. One-half of the patients were between 55 and 65 years old. There were, however, three cases in young girls under 20 and three in persons over 70. Forty-five out of 68 operable cases had radical operations performed. Only 5 died. Twenty-nine amputations of the tumor were done, with three deaths; 15 resections, with two deaths; and one excision through the perineum. Twenty-six were in women, 19 in men. Prutz adds to these two amputations for recurrence, with one death. In 38 cases a preparatory operation was made; in 19 resection of the sacrum. In 11 exarticulation of the coccyx, and in eight temporary reduction of the sacrum. Out of four perineal amputations, four vaginal operations, and one excision through the perineum, there were no deaths. Though the abdomen was opened 22 times, peritonitis occurred but twice, one of which cases was due to secondary infection. Infection also caused death from laceration of the intestine. Death resulted once from hemorrhage from the hepatic artery; and once from shock. The mortality for the past three years is four times that of the two years previous. Out of 20 cases operated over three years ago, six have had no recurrence. Eleven cases have died with metastases, over a year after operation. Of the 45 cases operated, 17 are still alive. In 13 patients colostomy was performed, three of whom died, six lived for an average of seven months, and one lived almost two years. Temporary resection of the sacrum Prutz considers dangerous. It is often done unnecessarily. If it must be performed, he prefers Gussenbauer's method. In 13 cases, not including the vaginal operations, part of the posterior wall of the vagina was removed; in four cases, part of the uterus. The ureter was injured twice. But the bladder, prostate and urethra were uninjured. In suturing the intestine, circular sutures were employed. In three cases the upper end of the intestine was invaginated. In 28 cases a sacral anus was left. In 25 cases the intestinal end was twisted

according to Gersuny's method. The histories of some of the cases are given, and the technique of the operations described. Colostomy was done by von Hacker's method, when necessary. [M. O.]

20.—Carcinoma nowadays requires excision of the neighboring lymph-glands. In cases of cancer of the lower lip, both submental and submaxillary lymph-glands, on both sides, are affected. Here a recurrence is often seen after operation. After reviewing the subject, Stieda describes an operation for extirpation of these lymph-glands by cutting a semicircular flap of the skin and platysma, along the under surface of the inferior maxilla. By turning the flap back, as far as the hyoid bone, the glands on either side may be removed. [M. O.]

21.—Sultan describes his experiments upon cats and dogs in a study of the function of the thyroid gland. From these results he concludes that total extirpation of the thyroid gland in dogs and cats causes symptoms of a severe, specific disease, unless accessory glands are present to assume its function. Extirpation of one-half of the thyroid gland is well borne. [M. O.]

22.—During the past five years, von Eiselsberg performed 18 radical operations for umbilical hernia. In all he saw 22 patients, 20 of whom were adults, one a girl of one year, and one a new-born babe. The infant, now a year old, still wears a binder. Of the 20 adults, 4 were incarcerated; of the others, five could be reduced. Seventeen of the 20 were in women. Eleven were between the ages of 30 and 40 when the hernia appeared. The majority of cases had existed five years. In five cases the hernia followed difficult pregnancy. These tumors, which had been reducible, later became irreducible. In the majority of cases there were no symptoms when the hernia appeared. Eleven of the cases had worn some abdominal support until operation. In size the herniae varied from a walnut to a man's head. Busse divides the herniae operated into four classes: the flat, stalkless, herniae, 6; the pedicled herniae, 3; the nodular, omental herniae, 2; and the irregular, mostly reducible herniae, 7. Six cases of the 18 operated were performed by Condamine's method. Of them all only two died. Eight of the others have had no recurrence; six have returned, and the results in two cases are unknown. Those with large herniae had recurrence generally. After a discussion upon the modern operations for umbilical hernia, Busse gives the histories of the 21 other cases reported. [M. O.]

23.—Charmont has collected von Eiselsberg's 29 cases of fecal fistulae and artificial anus. These he divides into 7 groups. In the first group is one case of congenital umbilical fistula, which was cured by excision of the navel. In the second group are 12 cases of fecal fistula and six cases of artificial anus following incarcerated herniae. Following operation in these 18 cases, but three deaths occurred. The next group contains one case of fecal fistula after appendicitis, which recovered. In the fourth group are two cases of tuberculous fistula, and one with typhoid. In the fifth group is one case of fecal fistula following parametritis. In the sixth group are two cases following tumors, with one death, and three cases of artificial anus from unknown cause form the last group. The case histories are given in full with a detailed description of the different operative procedures undertaken. In all, 22 operations were performed for fecal fistula, seven for artificial anus. Fourteen were in men, 13 in women, and two in children. Nineteen fistulae were inguinal, 11 on the right side. The inner opening of the fistula was in the small intestine in 21 cases. Diagnosis was not difficult. Two methods of laparotomy were performed: in nine cases the incision was made from the fistula; in 20 cases an independent incision was made. Resection of the wall of the intestine was done 18 times; wedge-shaped excision four times, and resection of the intestine, 18 times. Anastomosis followed by Woelfler's method of circular sutures 11 times, by the Murphy button twice, and by lateral and axial apposition once. Of the 29 cases, recovery resulted in 23; 4 patients died, and two were unimproved. Only one death was due to operation, a purulent peritonitis resulting. Charmont concludes that radical operation for fecal fistula and artificial anus is easily performed by resection of the intestine followed by sutures, with laparotomy. [M. O.]

24.—In operations upon the stomach there are three great dangers, infection, collapse and the post-operative

stagnation of the gastric contents. To prevent infection the stomach should be washed out once the night before the operation, and again an hour before operation. Finally, just before operation, the secretion of the stomach should be removed with the stomach tube. Fresh ulcerations will contraindicate gastric lavage. After operation, the dressings should be left undisturbed until the stitches are to be removed. To prevent collapse, normal salt solution should be injected subcutaneously; Schleich's infiltration anesthesia should be used whenever possible; and the body heat must be maintained, etc. After operation there is often a loss of motor power in the stomach, a reaction to the operation, with stagnation of the contents of the stomach. The gastric contents can be easily drawn off through a stomach tube on the second day after operation. Inanition and death may follow this gastric atony. Both functional and mechanical disturbances occur, and occasionally hemorrhage. Stieda lays great stress upon the use of the stomach tube before and after gastric operations. [M. O.]

25.—The diagnosis of tuberculous coxitis is no longer difficult, when Röntgen photographs are taken. Ludloff, after discussing the many treatments suggested, concludes that all cases should be put in plaster first, in the pathological position. Only when the contracture is so great that the patient cannot walk should "redressment" by Dollinger's method be done. As soon as the plaster stocking is dry, the patient should stand up and try to walk. If an abscess exists, it should be opened and treated with an injection of iodoform and glycerin before the plaster is applied. The plaster should then not cover the fistulae, but leave windows over them. Should old fistulae and fever exist, the patient must be kept in bed; then, should no improvement appear, resection with removal of the diseased tissue must be performed. The plaster bandage should remain unchanged for months. During this time the condition of the skin and of the general economy must be improved. When all pain has disappeared, a movable apparatus can take the place of the plaster stocking. This treatment should extend over years. If, even then, the position is poor, an osteotomy below the trochanter should be performed. [M. O.]

26.—Stieda reports 5 cases of coxa vara. The first case occurred in a boy of 16, following a fall from his horse. There was traumatic coxa vara, upon the right side. The next two cases were due to separation of the epiphysis of the femur, in girls of 12 and 15, due in the former, to osteomyelitis. The two important symptoms are spasm of the muscles and an increase in the patellar reflex. These are well shown in the last two cases, a boy and a girl of 17. Both cases were complicated by arthritis. The Röntgen photographs are excellent. General tonic is indicated, with extension, massage, and faradic electricity. The results are often excellent when the extension is stopped early. [M. O.]

27.—Sultan describes, with diagrams, an apparatus for applying permanent extension in fracture of the humerus, which he has used with success in the dispensary. It is inexpensive and practical. [M. O.]

28.—Ehrhardt describes two cases, in young people of 20, with progressive muscular atrophy, in whom von Eiselsberg sutured the two scapulae together. There had been great weakness in the shoulders and arms. Silver wire was used, and a process of the bone grew out, joining the two shoulder-blades. The improvement in power in the arms was striking. Ehrhardt describes the technique of the operation in full. [M. O.]

7. Agnathia, and the Condition of the Tongue that Occurs in Connection with it. KUSE.

8. Speech upon the Commencement of the Clinical Activity of the Clinic for Womens' Diseases in the University of Strassburg. H. FEHLING.

1.—Fuchs has employed vaporization of the uterus for various forms of endometritis, and particularly for profuse menstruation. He has performed a series of experiments upon uteri removed post mortem, in which he has found that the temperature rarely exceeds 100° C., but that it is exceedingly important that the cavity of the uterus should be of uniform diameter throughout. The action he considers, consists essentially in a burning of the mucous membrane of the uterus to the first or second degree, and as a result there is usually a sloughing and discharge of the mucous membrane at some time after the application. In cases of myoma, particularly the submucoid and polypoid varieties, the method should not be used. He reports a few cases and then gives a table and some figures showing the results of 22 cases treated by this method. In many of these curettment had been performed without result. In the majority of these cases the uterus was enlarged, and after the operation it became smaller in 9 of the 13 cases that could be carefully examined. In one case it is possible that a synechia formed in the upper portion of the cavity. [J. S.]

2.—Lachman reports the results of 33 cases in which cauterization of the uterus with super-heated steam, was employed. Atmocauterization is capable of producing bad as well as good results. Sometimes the hemorrhage stops, in other cases it continues or the patient grows worse. The conditions for which it was employed were polypoid endometritis, suppurative dysmenorrhea, inoperable carcinoma of the body of the uterus, climacteric dysmenorrhea, flooding, etc. The paper is still unfinished. [J. S.]

3.—Von Graefe approves strongly of the wedge-shaped incision of a portion of the cervix in cases of descent of the uterus, with hypertrophy of that part. The operation frequently gives excellent results. He reports in particular, the case of a woman in whom it was performed, and who was able subsequently, to accomplish the severest forms of daily labor. In another case, a woman suffering from hysteria, her condition was made worse by the operation. He therefore does not approve of this operation in hysterical and neurasthenic cases. It is important to prevent any severe work during the period of subsequent treatment. There does not appear to be any favorable influence upon chronic hyperemia and enlargement of the body of the uterus. Conical enlargements are distinct indications for its employment. [J. S.]

4.—Theilhaber discusses the various theories that have been suggested to explain the occurrence of dysmenorrhea. He defines this condition as that in which actual colic pains occur in the course of menstruation. These usually occur in the sacral region and radiate forward. From time to time there are severe exacerbations. He does not agree with Möricke that the condition is always, or usually associated with actual disease of the sexual organs, because 1st, it occurs most frequently in young women and maidens who have never borne children, and have no anatomical changes. 2d, it varies in degree from period to period. 3d, it may disappear entirely as the result of change of residence, and 4th, it may or may not be present when there is distinct local disease. However, certain forms of uterine colic may be produced by diseased conditions such as the polypoid and submucous myomata, or perimetritis. Among the favorite theories are: 1st antifixion, but there is much reason to believe that during the congestion that occurs during menstruation the uterus is straightened. 2d, stenosis of the cervix or of the inner os. As a matter of fact stenosis almost never occurs unless some operative interference has been undertaken. Others believe that endometritis and metritis are active factors, but Theilhaber has treated cases of extreme endometritis in which menstruation was painless. The ovaries and tubes have also been accused, and it is not entirely impossible that spasms of the tubes might actually produce pain,

although this seems *a priori* unlikely. Finally such remote things as movable kidneys, and parovarian varicocele have been considered active agents. Fliess has suggested that the pain is entirely due to reflex irritation from the sexual spot on the inferior turbinated bone of the nose, and he claims that he is able to relieve it entirely by painting the spot with cocaine. It is possible that any relief that is produced by this treatment is due to the influence upon internal circulation. The paper is still unfinished. [J. S.]

5.—Glaevecke reports the case of a girl of 11 suffering from bronchiectasis which was associated with severe paroxysms of coughing. She was weakened and rachitic, and suddenly developed prolapse of the mucous membrane of the urethra. An attempt to cure this by reposition having failed, the prolapsed part was amputated, and the mucous membranes attached to the skin by sutures. The result was perfect. He has studied the literature of this condition, and as a result draws the following picture of it. The etiology is rather indefinite. The old theory that it was due to local irritation appears to be disproved by the fact that the majority of cases occur in young children; 66% of all recorded cases in girls under 14 years of age, and 22% in women who have passed the climacteric. The majority of patients are weak and debilitated. The symptoms are usually very slight. There is usually slight hemorrhage, sometimes pain, and occasionally, if gangrene of the prolapsed part occurs, fever. The most important symptom is difficulty in micturition. The condition can readily be recognized by inspection. The prognosis is favorable. The treatment consists in attempts at reposition, or if these fail, as they almost always do, in amputation by various methods of the prolapsed mucous membranes. Of all hitherto suggested, he prefers the method of Kleinwächter, which was the one he employed. [J. S.]

6.—Schenk, as a result of 2 cases reported by Beutner, in which in attempts to sound the uterus, extraordinary lengths were obtained, (in one case a dilator entered for 14 cm., and in another, the sound, for 20 cm.) gives a brief summary of the discussion aroused by these reports, and mentions some cases in which similar extraordinary results were obtained. He then reports the case occurring in the Clinic of Saenger, of a woman, 38 years of age, who had had 9 children. When examined it was found that the uterus was slightly enlarged, and that there was severe laceration of the cervix. In the preparation for operation the sound was introduced and found to pass without resistance for 20 cm. A diagnosis of perforation was made; immediate laparotomy performed, and 3 perforations actually found at the fundus of the uterus. The substance of the uterus was extremely friable. The patient recovered completely, and was discharged cured. Schenk suggests that the repeated births had brought about a peculiar pathological condition of the uterine muscle. [J. S.]

7.—As a result of Von Winkel's article upon agnathia Kuse has undertaken at Ort's suggestion, a careful study of 5 cases of this condition, in the museum at Göttingen, in order to determine whether any fragments could be discovered that resembled the lower jaw. The first case exhibited a great variety of malformations. A very minute fragment was found that was possibly the inferior maxilla. In the second case, also very greatly deformed, a distinct fragment was detected that was unquestionably the undeveloped lower jaw. In the third and fourth cases rudimentary lower jaws were also found. Finally in the 5th case, a monstrous lamb, the relic of the lower jaw was not found. He concludes that in his four human cases the rudimentary lower jaw was present. In 2 of these cases there was a rudimentary condition of the hyoid bone, but in all of them the horns of the hyoid bone and the larynx were well formed. The cause of the condition is difficult to determine, but was probably not due to pressure by amniotic folds. The thyroid glands are frequently well formed. [J. S.]

8.—Fehling gives a brief historical description of the obstetrical clinic in Strassburg, and calls attention to the great importance of a complete study of the normal cases. [J. S.]

WIENER KLINISCHE WOCHENSCHRIFT.

May 9, 1901. (XIV Jahrgang, No. 19).

1. The Clinical Diagnosis of Renal Infarct and Renal Colic. RUDOLF SCHMIDT.
2. The Effect of Suprarenal Extract upon the Nasal and Laryngeal Mucous Membrane. L. HARMER.
3. Lacerations of the Vaginal Vault During Labor. II. LUDWIG.

1.—Will be abstracted when concluded.

2.—After the internal use of extracts of the ductless glands had become general, ophthalmologists and laryngologists began to employ them locally. This is especially the case for suprarenal extract, which is a powerful vaso-constrictor. The rich literature of the subject has been fully reviewed. Harmer has used suprarenal extract upon 32 patients, 22 of whom had hypertrophic rhinitis. The inferior turbinal became paler and decreased in size after the application of a 10% solution of suprarenal extract. The effect was noticeable in two minutes. With true hypertrophy, several applications were necessary to cause any change, some cases remaining unaffected. As a local anesthetic it had no effect in the nose. In the larynx he used a 50% solution, upon 9 patients. Four of these cases are reported, in which the suprarenal extract with cocaine had a decided anesthetic effect. The last case was one of edema over the right arytenoid cartilage, which diminished with the application of the suprarenal solution. Harmer concludes from his experience that it decreases swelling of the mucous membrane, and aids cocaine in producing anesthesia. Experimentally it has been shown that extirpation of both suprarenal capsules is followed by a decided decrease in the blood pressure; and that intravenous injection of suprarenal extract markedly increases the blood pressure. There is no doubt that it exerts an influence upon the peripheral blood vessels. This vaso-constriction explains the anesthesia also. Harmer advises its use in hyperemia of the mucous membrane, and in the larynx, whenever long treatment must be given. To lessen the amount of cocaine needed to produce local anesthesia, it is of great assistance. It should be used in people who cannot stand cocaine. As an hemostatic Harmer considers it as dangerous as cocaine. [M. O.]

3.—Injury to the uterus or to the vaginal vault during child-birth may be accompanied with dangerous hemorrhage or laceration of the perineum with infection following. Laceration of the vaginal vault by itself is rare, as it is generally combined with laceration of the cervix. After a review of the literature, Ludwig has tabulated 73 cases, some of which are his own observations. In 45 of these, spontaneous rupture of uterus and vagina occurred; 13 were due to injury; in 15, rupture of the vagina occurred alone, probably due to violence; and in 5, rupture occurred in the vagina primarily, but was continued into the cervix. Lacerations occur spontaneously when a great disproportion in size exists between the child and the maternal tissues. This occurs in a narrow pelvis, in pendulous abdomen or when the uterus has been sutured in place by a previous operation. Other causes are very large fetal head, abnormal position, very strong labor pains, great abdominal pressure, a fall, an accident, abnormally small or undeveloped vagina, pathological changes in the elastic fibers of the vagina, carcinoma, etc. Spontaneous lacerations may occur with injury from the hand, instrument, forceps, etc. These lacerations are not seldom seen in multiparae, because pendulous abdomen and abnormal position are commoner, later children are larger, and scars or other anomalies of the vagina exist. The position of the laceration depends upon the cause; with pendulous abdomen it is in the posterior or lateral wall of the vagina. The posterior vaginal wall is most frequently lacerated because it is least protected. Uterus, peritoneum, and bladder may also be extensively torn. The intestines and omentum generally protrude through the laceration. Before rupture there are few symptoms, when rupture occurs the pain is severe. After rupture there may be but few subjective symptoms,

but there are hemorrhage, cessation of the labor pains, disappearance of the fetus, and all the signs of beginning peritonitis. The diagnosis of laceration of the vaginal vault is probable when rupture of the uterus has occurred. The prognosis is always grave. The treatment consists of delivery of the child and attention to the laceration. Hemorrhage must be stopped, and infection prevented. Laparotomy is generally necessary. Prophylactically a woman with a large abdomen should wear a binder during pregnancy. Care must be taken when labor occurs, especially should any operation be needed. Ludwig adds the histories of two more cases, recently reported, and a long bibliography. [M. O.]

May 16, 1901. (XIV Jahrgang, No. 20).

1. The Influence of Alcohol upon the Course of the Infectious Diseases. MAX GRUBER.
2. Further Research upon the Etiology of Acute Rheumatism. GUSTAV SINGER.
3. The Clinical Diagnosis of Renal Infarct and Renal Colic. RUDOLF SCHMIDT.

1.—From a careful collection of the many experiments made upon the various animals to show the effect of alcohol in the infectious diseases, Gruber concludes that it should never be given unless the patient is near collapse. For all the experiments prove that alcohol, even in small doses, weakens the resistance of the organism, and so favors the action of the invading microbe. In collapse, alone, was life prolonged by the use of alcohol. Beside this unfavorable effect in disease, experience also shows its dangerous effect upon posterity, as it is the cause of still born infants, with more or less widespread fatty degeneration. [M. O.]

2.—Singer reports five new cases of acute articular rheumatism and two cases of rheumatic chorea, in five of which streptococci were found, in the two others, staphylococci. Drawings of the microscopical pictures are given. After reviewing the later literature upon the subject, Singer reiterates his conclusion that the streptococcus is the cause of acute articular rheumatism, though it has only been found in the heart and lungs, never in the joints. [M. O.]

3.—Emboli in the kidney are frequent, yet the diagnosis is rarely made clinically. Schmidt, after quoting what little he could find in the literature upon the diagnosis of renal infarct, reports 7 such cases in detail. Two of the cases were under his own observation. From these cases it is evident that pain occurs in the kidney region, with disturbance in the secretion of urine, and changes in the urine. There is oliguria, albuminuria, but rarely hematuria. The pain, which may be intense, varies in character and location. Pressure increases the pain. The pain gradually decreases in intensity. Many constitutional symptoms are also present. When renal colic occurs, the physician must determine whether the cause is intrarenal, when the pain is circumscribed, the kidney is sensitive to pressure, and the pain is constant; or whether it is extrarenal or ureteral, when the pain radiates down the ureter, is intermittent in character, with tenderness along the ureter. The cause of intrarenal colic may be torsion of the pedicle of a floating kidney, sudden congestion of a tumor, acute exacerbation of a chronic nephritis, or a renal infarct. Pain upon pressure over the kidney is more often seen in renal infarct than in chronic nephritis. A high pulse tension speaks against renal infarct. The colic in renal infarct will disappear with rest in bed. Apoplectic form pain is peculiar to renal infarct, and severe hematuria is rare. Besides, intense albuminuria, without casts, appears and disappears suddenly with renal infarct. The presence of enteroptosis with renal infarct is unfavorable. Lying upon the healthy side will increase the pain in renal infarct. Should the renal artery be occluded, urinary symptoms may be absent. Oliguria or anuria appears when both kidneys contain infarcts. Then the desire to urinate will also be absent. [M. O.]

ANNALES DE GYNECOLOGIE ET D'OBSTETRIQUE.

March, 1901.

1. On the Recurrence of Ectopic Pregnancy. (A Critical Study of 96 Cases). II. VARNIER and C. SENS.
2. Polycystic Liver a Cause of Dystocia. Association of Cystic Degeneration of the Liver and Kidneys in a Fetus Affected with Multiple Malformations.

PORAK and COUVELAIRE.

1.—Varnier and Sens have made a most extensive study of extrauterine pregnancy, 96 cases of which have been reported in the literature. They conclude from their investigations that recurrence of extrauterine pregnancy is much more frequent than has been imagined. This recurrence has habitually taken place in the tube of the opposite side. Of the 43 cases of recurrent pregnancy in which the side occupied by the pregnancy is noted, in 16 cases did it occur on the left side, and in 27 cases on the right. The time which had elapsed between the first and second pregnancy varied from one month to 12 years. In six cases only did a normal intrauterine pregnancy occur between the first and second ectopic pregnancies. There seems to be some tendency on the part of the second pregnancy to develop along the same line as the first. The authors have grouped the cases in tabular form according as to whether or not the diagnosis has been proved absolutely for each pregnancy. [W. A. N. D.]

2.—Porak and Couvelaire report an exceedingly interesting case of dystocia due to oversize of the fetal abdomen. The cause of this excessive size of the fetal body was a polycystic liver, containing 350 grams of liquid, associated with a cystic degeneration of both kidneys and multiple malformations (encephalia, achondroplasia, supernumerary fingers and ears, rudimentary external genitalia). He remarks that cystic liver as a cause of dystocia is exceptional. There are but few cases recorded of liver tumors in most of which the tumor was solid. He can find but four cases of cystic liver, namely, those of Witsel, Guéniot, Bagot and his own. He presents a short review of these cases. [W. A. N. D.]

April, 1901.

1. The Treatment of Complete Uterine Rupture by Total Abdominal Hysterectomy with Three Cases. CORNELIUS CRISTEANU.

1.—Christeanu during the last three months had occasion to observe three cases of uterine rupture produced at the time of delivery. From a study of the symptoms and the results of intervention, he has arrived at conclusions which do not quite conform to those given in the classical treatises. The mortality of the accident will diminish with the rapidity of intervention. According to most authors, the first indication, save when the fetus has passed into the abdominal cavity, is immediate extraction by version, forceps or basiotripsy. After rupture the uterus normally contracts upon itself, and the traumatic orifice becomes so small as scarcely to permit the introduction of the hand. The author is certain that in every case, even in those in which the fetus has not escaped into the peritoneal cavity, the proper treatment is to perform a laparotomy. In other words, a rupture of the uterine tissues is an absolute indication for a laparotomy, with extraction of the fetus through the abdominal wound, after which the patient, in the Trendelenburg posture, a total abdominal hysterectomy should be performed and the peritoneum sutured and hemostasis made perfect. Toilet of the peritoneal cavity should then be made, together with vaginal drainage, followed by absolute closure of the abdominal wall by two varieties of stitches, cat-gut and silk. If needed, an injection of serum during and after intervention may be made. [W. A. N. D.]

BOLNITCHNAIA GAZETA BOTKINA.

May 30, 1901. (Vol. XII, No. 22).

1. A Milky Non-chylous Transudate. V. V. ZAVIALOFF
2. On the Albuminous Substances and Capsules of Bacteria and Fungi. K. I. IVANOFF.
3. A Case of Priapism. P. I. GUNDEGGER.
4. Ruptures and Traumatism of the Thoracic Duct.

B. K. FINKELSTEIN.

1.—Zavialoff made a careful study of a specimen of ascitic fluid obtained from a patient suffering from chronic nephritis. It belonged to the group of exudates first classified by Lion in 1893 as "ascites laiteuses non chyleuses." These effusions are milky in appearance, closely resembling chyle, from which, however, they differ, microscopically, by the absence of fat globules or granules, and, chemically, by not being cleared up by ether. In all 16 cases of such transudates are recorded in the literature.

Various theories have been advanced as to the cause of the opalescence of the fluid, but so far opinions are divided. The specimen studied by the author was strongly opalescent, closely resembling an alkaline solution of glycogen. The latter, however, was found absent. The opalescence could not be removed by filtration, ether or potassium hydrate. On boiling no coagulation took place. The addition of acetic acid to the cold fluid produced no precipitate, but on boiling a fine flocculent precipitate occurred which gradually settled to the bottom of the tube, leaving a clear supernatant fluid which gave a slight biuret reaction. A similar precipitate was obtained by the addition of an equal volume of a saturated solution of ammonium sulphate. The precipitate could be readily removed by filtration, and when dissolved in water produced an opalescence similar to the original fluid. That this substance was not globulin is proven by the fact that it was not coagulated by heat. Furthermore, by the addition of a 5% solution of hydrochloric acid and boiling, a substance reducing Fehling's solution was obtained. This reaction places the substance among the glycoproteids; and inasmuch as it was not precipitated by acetic acid, thus differing from mucin, it belongs to the group of mucoids. To this group, according to the latest researches of Leven, belong also the amyloids. The latter, as shown by Kravkoff, possess also a form which is soluble, and could therefore be circulating in the blood. These facts lead the author to the conclusion that the presence of mucoid in the ascitic fluid may indicate amyloid degeneration of the organs. [A. R.]

2.—Ivanoff demonstrated the presence of typical nucleoproteids in the protoplasm of bacteria and fungi, while the capsules of bacteria were found to contain a substance identical in its composition to chitine. In his analysis he employed Kravkoff's method, which consists in the precipitation of the bodies of the bacteria or crushed fungi by a solution of acetate of copper and subsequent treatment with a weak (not over 1%) solution of caustic alkali, which extracts all the albuminous substances. The washing with alkali should be continued until the disappearance of the biuret action. The residue contains the capsules, hemicellulose and carbohydrates of the types of glycogen and starch. On the addition of weak hydrochloric acid everything is dissolved, except the capsules. The latter are washed carefully in water, alcohol and ether, and are analyzed. To obtain the albuminoid substances the first three alkali washings are treated with an excess of acetic acid, and the sediment washed in water, alcohol and ether. [A. R.]

3.—Will be abstracted when concluded.

4.—Finkelstein reports the case of a peasant who, during an assault by unknown persons, received two wounds in the chest, one at the presternal notch, the other on a level with the fourth rib. As a result of these injuries the man developed what was diagnosed and proved to be a chylothorax. 2000 c.c. of fluid (chyle) were evacuated from the pleural cavity on each of two occasions. There was no temperature elevation, except on the ninth day after the first aspiration, when the temperature rose to 38.5. The man made a good recovery. An extensive bibliography is given, including a tabulation of 22 cases of injury to the thoracic duct, recorded in the literature. As to treatment, the author recommends simple plugging of the wound. In uncomplicated chylothorax aspiration is sufficient. Forced nourishment and perfect rest will hasten recovery. [A. R.]

The Sedimentation of Sputum.—Finck, in the *Revue Médicale de l'Est*, May, 1901, No. 9), reviews the subject of sedimentation of sputum. When the number of bacilli is small and the amount of expectoration large, some method must be employed to reduce the quantity of sputum. In 1886, the subject was first approached by Philip, who left the sputum a day in a moist warm atmosphere. The addition of many substances, boiling, etc., have been suggested. The best method is that devised by Spangler, who adds distilled water to separate the masses. Concentrated soda solution is added, then pancreatin. This is then kept in the oven at 37°C. for two hours, when a few drops of carbolic acid are added. After 16 hours, the liquid is poured off and the sediment examined. Centrifugation may be added to this. It is then easy to find bacilli among quarts of sputum. [M.O.]

Special Article.

HUMAN AND BOVINE TUBERCULOSIS.

By LEONARD PEARSON, B. S., V. M. D.

Dean of the Veterinary Department of the University of Pennsylvania
and State Veterinarian, Pennsylvania.

Professor Koch's address at the recent British Congress on Tuberculosis has excited considerable interest on account of his statement that we have little to fear from the use of tubercle bacilli bearing food products of tuberculous cattle. Fortunately, his reasons for this opinion are fully stated, so we are able to examine the ground upon which this new theory rests.

Koch has observed that human tuberculosis is not readily inoculable in cattle and concludes that it differs from cattle tuberculosis. This in itself is not construed to show that men are not susceptible to bovine tuberculosis, although it is implied that if the disease will not pass in one direction it will not pass in the other.

The real argument for the new theory is stated in the following sentences: "That a case of tuberculosis has been caused by alimenta can be assumed with certainty only when the intestine suffers first—that is, only when a so-called primary tuberculosis of intestine is found. But such cases are extremely rare."

This claim deserves the most careful consideration, on account of the commanding position of its author and also from the fact that considerable effort is being made to exclude from the market tubercle bacilli bearing meat and milk; effort wasted if the claim is true.

But it is erroneous to assume that the solution of this question can be found in the distribution of the lesions of tuberculosis in the body. It has been shown in the most unmistakable way by many feeding experiments conducted under the auspices of the Pennsylvania State Live Stock Sanitary Board, that, contrary to the early belief, animals fed tubercular materials may develop primary tuberculosis and, in some instances, fail to show lesions in any other organ. It is strange that Prof. Koch failed to observe the importance of this point, for in his address he says: "Among the animals (swine) that have been fed with sputum no trace of tuberculosis was found, except here and there little nodules in the lymphatic glands of the neck and, in one case, a few grey nodules in the lungs. In these cases the animals were infected by feeding, but did not develop tuberculosis in the intestines first, or at all." A little later he says: "The animals that had eaten bacilli of bovine tuberculosis have without exception (just as in the cattle experiment) severe tubercular diseases, especially of the lymphatic glands of the neck and of the mesenteric glands, and also *extensive tuberculosis of the lungs and spleen*." Here, again, is pulmonary tuberculosis from feeding, complicated, it is true, by disease in other organs; but who could say, without knowledge of the history, by what channel the bacilli entered?

The whole question, therefore, is strictly bacteriological, the question being: Is the bovine tubercle bacillus virulent for man?

It is interesting to note that Dr. Theobald Smith, of Harvard University, was the first to discover and report upon certain cultural, morphological and

pathogenic differences between human and bovine tubercle bacilli, and that since 1898 investigations have been conducted under the auspices of the State Live Stock Sanitary Board for the purpose of comparing tubercle bacilli from human and bovine sources. The comparisons that have been made were reported in part at the recent Congress on Tuberculosis in London by Dr. M. P. Ravenel, whose paper will appear in the *Philadelphia Medical Journal*. Dr. R. R. Dinwiddie, of the Agricultural Experiment Station of Arkansas, has also reported his extended studies of the same problem. It thus appears that this question of the relationship between human and bovine tubercle has received more attention in this country than in any other. The work that has been done here shows very clearly that for experimental animals tubercle bacilli from cattle are in all cases as virulent and usually very much more virulent than tubercle bacilli from man. The animals used in these comparisons include herbivora and carnivora and species that are resistant as the horse, goat, rabbit and dog, and species that are vulnerable as the guinea pig, cat, swine and cattle.

In the face of the fact that the bovine bacillus is so constantly more virulent than the human bacillus for experimental animals of so widely different species and habits of life, it does not seem safe to conclude because the human bacillus is not especially virulent for cattle that the bovine bacillus is nonvirulent for man. Koch has said that this question could be settled positively only by the impossible expedient of inoculating a person with bovine tubercle bacilli. But it has happened that such inoculation has already occurred accidentally in several instances. A number of men have contracted tuberculosis and several have died from infections sustained in making postmortem examinations on tubercular cattle. These accidental cases show beyond peradventure that the bovine tubercle bacilli may under some conditions be virulent for man.

With evidence of this sort before it, the British Congress could do little else than it did in recommending the continuance of all official and private efforts to repress tuberculosis of cattle and the institution of a thorough scientific inquiry into this whole subject of the relation of human and bovine tuberculosis.

Retained Placenta.—It is rare for the placenta to be retained in a cavity, like a bursal sac, the after-birth not being able to pass the constricted outlet. This pocket is formed below by the greatly contracted cervix uteri, and above by the less contracted uterus, about the insertion of the placenta. In discussing this variety of retained placenta, called in French, "*enchâtonnement*" of the placenta, in the *Journal des Sciences Médicales de Lille*, (1901, No. 19) Dervaux states that it is due, in a normal uterus, to too early contraction of the uterus after child birth, or to "hour-glass" contraction of the uterus, caused by retained or adherent placenta. Encysted placenta follows. It should be treated with anti-spasmodics and uterine dilatation. It is also seen in an irregular, coralloid or double uterus. Dervaux reports a case of coralloid uterus in a girl of 22, in whom the placenta was retained. Under an anesthetic, the hand, introduced, found a second, upper, cavity, from which the placenta was slowly detached. In this variety, artificial delivery of the placenta will be necessary, though a difficult proceeding. [M. O.]

*Dr. Ravenel's paper will be published in THE PHILADELPHIA MEDICAL JOURNAL synchronously with its appearance in the *University of Pennsylvania Medical Bulletin* in September.

THE IMPORTANCE OF A MORE GENERAL STUDY OF
DISEASES OF THE NERVOUS SYSTEM.*

By WHARTON SINKLER, M. D.,

of Philadelphia, Pa.

Physician to the Orthopedic Hospital, and Infirmary for Nervous
Diseases.

Forty years ago but little interest was taken in diseases of the nervous system, and, in fact, at that time but little was known of them. It is true that at about the middle of the nineteenth century some earnest workers in neurology made discoveries in connection with the pathology and physiology of the nervous system, which aroused the world to the fact that there was something worth knowing in nervous diseases, but it was not until the latter half of the century that real progress began to be made in these disorders. In 1863, Broca made the first contribution of real importance in cerebral localization when he announced the fact that the cerebral seat of spoken language was in the third frontal gyrus, and this convulsion has been known by his name to the present day. In 1858 Duchene published his classic paper on a form of paraplegia, which he called "Locomotor Ataxy;" and Trousseau, by his reference to this communication in his famous lectures, gave it a widespread reputation. We must give credit, however, for the actual discovery of the disease to Todd, an English physician, who accurately described the symptoms in 1847, and expressed his belief that the pathological lesions were located in the posterior columns of the cord. Romberg, in 1851, also wrote of locomotor ataxy, and pointed out a symptom which is an early and important feature—namely, the inability of a patient suffering from this disease to stand with the eyes closed; hence the name "Romberg's sign," which is still in use. Duchene thought the pathological anatomy of locomotor ataxia was to be found in the cerebellum, but Charcot, Vulpian, Leyden, Lockhart, Clark and others demonstrated his error and showed that the original idea of Todd was the correct one—namely, that the earliest lesions of the disease are to be found in the posterior columns.

The true progress in our better understanding of nervous diseases has been undoubtedly due to the study of the localization of the lesion. This has given a strong impulse to the thorough and intelligent investigation of diseases of the nervous system, and has placed on a firm and scientific basis the study and diagnosis of all these affections. Probably no one has added more of value to the subject of localization of nervous diseases than Hughlings Jackson. His papers on this subject began to attract attention in 1863, and from that time until the present he has been a constant and brilliant contributor to the subject. Ferrier, through a series of experiments on the lower animals, especially the monkey, has demonstrated the functions of different areas of the brain. His first paper was published about 1876. It would be invidious to mention other names, because since the time of

Broca so many have contributed to this subject that one could not undertake to say whose work has been of most importance.

In 1865 no medical schools in this country gave a course of lectures on nervous diseases, nor was any special attention paid to the subject clinically or otherwise by the teachers. About this time, however, an interest began to be awakened in this country, due, to some extent, to a consequence of the large number of nervous diseases which resulted from the war, either from wounds or otherwise, and probably the researches of Weir Mitchell and W. A. Hammond had much to do with creating this new interest. In 1871 the New York Neurological Society was organized, and in 1875 the American Neurological Association, and a few years later the Philadelphia Neurological Society came into existence; and now in Chicago, Boston, Baltimore and several other of the larger cities there are societies devoted to the scientific study of nervous diseases. In nearly all of the prominent medical schools there have been established in the past few years Chairs of Neurology, or courses of clinical lectures are regularly given on this subject. The growth of the study of nervous diseases has been somewhat slower in the South, but here its importance is being recognized. Some of the schools are giving courses on nervous diseases, and in every city of the South men are to be found with greater or less experience in nervous diseases. This is particularly notable in the asylums for the insane, which are in charge of men who are making scientific study of mental diseases, and many valuable papers on mental and nervous diseases have been contributed within the past few years by the medical superintendents of asylums in the South. Nevertheless, even now the general practitioner has not had forced upon him the necessity for a thorough acquaintance with nervous diseases. This is probably because they are not yet sufficiently studied, and other special subjects, notably gynecology, laryngology and ophthalmology seem to have attracted the attention of the general practitioner to a greater extent.

Another reason for the want of familiarity with the subject is, that there is a general impression that nervous diseases are obscure and difficult of comprehension. This is not the case. If one will only remember his anatomy and physiology, the diagnosis and localization of diseases of the nervous system become easy. It is of the utmost consequence that the practitioner should have a good acquaintance with neurology, for it is he and not the specialist who first sees the patient who is suffering from some nervous trouble in its incipency. The early recognition of all disorders of the nervous system is absolutely necessary, for it is in the prodromal stages of these affections that it is possible to arrest the onset of a disease, which, when once established, is irresistible. It is like the spadeful of earth which will stop the little stream in a crevasse which is the forerunner of a break in the levee, but in a few hours thousands of carloads will have no effect in controlling the raging torrent which rushes through the embankment.

There is probably no disease in which it is of more consequence to recognize the first symptoms

*The annual address read before the South Carolina Medical Association April 18, 1901.

than in paresis. The earliest symptoms are not conspicuous and are often transitory. The patient may seem somewhat erratic, and his actions and language may be little more than exaggeration of what is natural to him; but close observation will show that there is undue enthusiasm or excitability in regard to matters of individual interest; that there is some failure in memory, and that he has a less high ethical sense than formerly. Careful physical examination shows some changes in the pupils, probably a slight tremor of the lips in speaking, and a tendency to slurring of syllables and words in speaking may be noticed. These points should excite the suspicion of the observer and make further study of the case imperative. Paresis is most insidious in its onset, and it is only by careful study that the early diagnosis can be made. In its earliest stage it may be mistaken for neurasthenia combined with hysteria, for there are many symptoms common to both. The patient often suffers from headaches, insomnia, attacks of migraine, digestive disorders, which are attributed to nervous dyspepsia, and hypochondriacal depression. As the disease progresses faults of memory appear; words are misused in speaking or writing; the speech is affected, becoming hesitating and jerky, and certain words are pronounced imperfectly. For example, in saying a long word like "intelligence," some syllables are left out and the word elided, or sometimes the syllables are repeated. Then certain mental peculiarities appear; the patient's moral sense becomes blunted and the proprieties of life are not observed keenly; interest in important affairs gives way to inordinate enthusiasm about trifles; the patient gets careless about business; he constantly loses or mislays things, makes mistakes in money matters and business affairs; he confuses people with each other; he loses his way; he becomes extravagant in his purchases, believing that he has endless wealth, and is excitable, being easily angered and pugnacious, and exhibits tendencies to alcoholic and sexual excesses. At first the patient seems conscious of his not being in a normal condition, but later he is entirely oblivious of his changed state. After a period varying from a few months to several years, the prodromal stage is passed and the symptoms become more pronounced.

Physically, certain important symptoms are not conspicuous, namely, the articulation and handwriting. Marked tremor of the lips, tongue and facial muscles appear, and later there is general tremor, especially of the hands. Myosis, or pin-point pupils are frequently present; the pupils may be unequal, one being much larger than the other, or there may be irregularity in the shape of the pupil. The Argyll-Robertson pupil is also present in some cases. There is entire loss, or there may be exaggeration of the tendon reflexes; then comes muscular weakness, apoplectic or epileptic seizures take place, and finally the patient becomes emaciated and has various muscular disorders. Mentally, the symptoms become equally characteristic as the disease advances. Weakening of memory and judgment are noticeable; the patient becomes possessed of delusions of enormous proportions, either of an exalted or depressed nature. Hallucinations and illusions of various kinds are present.

Sometimes the patient is in a state of great exhilaration with the happiest ideas, and at other times he may be in a condition of the deepest melancholy. In the terminal stages there is a condition of dementia; the patient is unconscious of his surroundings, recognizes no one and is entirely imbecile.

As sixty to seventy per cent. of the cases of paresis have a history of syphilis, it is obviously important to begin with constitutional treatment as soon as the disease is recognized. Some writers allege that, if taken in the beginning, the disease may be arrested, but even if this be not true, and most neurologists take this view, it is often possible to delay the progress of the disease by appropriate treatment. Unfortunately, paresis is incurable, and sooner or later characteristic symptoms become established and the case terminates fatally. Nevertheless, even if no permanent good is done by treatment, the value of distinguishing the affection early is great. It enables the physician to so direct and order the life of the patient that he may be prevented from committing acts which would be distressing or humiliating to himself or to his family, and measures may be taken to preserve his estate from being squandered.

Paresis was formerly unknown among negroes, but since the war it is comparatively common. Berkley refers to this as "one of the results of Civilization and Syphilization" in that race.

Locomotor ataxia is another common neurosis the onset of which is often gradual and insidious. It is a disease which the general practitioner often fails to understand. I have been asked to see cases in consultation with the family physician, who informs me that he has already made a diagnosis of locomotor ataxia, and on examination I find grossly exaggerated reflexes and spastic gait. It is true that the patient has ataxia of station and gait, and that his disease is quite as incurable as tabes, but he has not the clinical features of the latter malady. Ocular symptoms are early in locomotor ataxia; quite often the first thing wrong which is observed is diplopia from paralysis of the sixth nerve. This may not last for more than a few weeks or months and usually disappears not to return. The pupillary reflexes may be lost before any other symptom is present, and there may also be myosis. If one sees a patient with pin-point pupils, it is always wise to examine for other symptoms of tabes. The deep reflexes are lost early, and severe attacks of neuralgia in the extremities may be a forerunner of the disease. In some cases the first thing noticed by the patient is inability to stand while his eyes are shut, while washing his face. Hammond relates the case of a man who found that, when mounting his horse, he could not put his foot into the stirrup without keeping his eyes upon it. When the disease is established, there is an array of symptoms which are distinctive, and should not be confounded with any other neurosis. The patient's walk is peculiar; he keeps his eye on the ground in front of him to preserve his equilibrium; his heels meet the ground first, and there is a general unsteadiness and inordination of the movements of the legs. The gait reminds one of a blind horse who steps high to avoid unseen objects. Inability to stand with the eyes closed for the shortest space

of time is present. The knee-jerks and other deep reflexes are abolished, but the plantar reflexes may be preserved. The pupils are often contracted and do not respond to light, but do contract and dilate in accommodating for distance, the so-called "Argyll-Robertson" pupil. The arms may be ataxic, and there is great awkwardness in the use of the hands, and if the eyes are shut the patient cannot employ the fingers for the simplest acts; for example, buttoning or unbuttoning the clothing. Sensation is greatly impaired and localization and tactile sense are poor. The slowness in the conduction of a touch from the extremities to the brain is characteristic. Gastric crises occur, characterized by violent attacks of vomiting and epigastric pain; and pain crises are frequent and distressing, the pain being lightning-like, shooting or darting through the limbs, or it may be boring in character and confined to a small area, no bigger than a fifty-cent piece. Usually the attacks of pain are most severe in damp weather, and are often barometer-like in foretelling a storm.

The disease progresses steadily from bad to worse; in some cases the advance is much slower than in others, and sometimes it may be arrested or greatly ameliorated, but it is never cured. If treated early much can be done. The patient can be taught how to take care of himself in the way of suitable clothing, and in the selection of a residence in a climate in which no violent changes of temperature occur. Medication is of but little service, but hygienic measures are of the utmost importance.

Another disease in which early diagnosis makes the difference between recovery and an incurable condition is Multiple Neuritis, which has of recent years become a recognized entity. Formerly it was confounded with tabes, myelitis and progressive muscular atrophy. I have been surprised, however, to find that even now it is not generally understood. In the past few months I have had two cases of complete and extensive multiple neuritis sent to me by excellent general practitioners, in both of which the diagnosis of hysteria had been made. One was alcoholic multiple neuritis and the other a remarkable case of general neuritis following an uncomplicated labor. One of the commonest causes of multiple neuritis is excess in the use of alcohol. The foot and wrist drop, hyperesthesia and tenderness of the nerve trunks and the mental disturbance are typical. If recognized early, and all alcoholic drinks are immediately withdrawn, the disease is soon cured, but if the patient is allowed to continue the use of stimulants in any form, the disease steadily becomes worse and ultimately reaches a fatal termination. I recall a case of alcoholic neuritis in which a correct diagnosis was not made, and the patient was allowed to take quite a considerable amount of whiskey, because it was felt that he needed it for its strengthening effect. The patient grew progressively worse and finally died.

Other forms of multiple neuritis are met with, and are usually toxic or of infectious origin. Thus diphtheria, typhoid fever or puerperal infection, and diabetes not uncommonly cause multiple neuritis. Certain drugs or metals absorbed into the system will also produce the disease. Lead mul-

tiple neuritis is quite common among painters and others who handle white lead. I have seen one extreme case in a young girl who used powdered white lead as a cosmetic. Arsenic may be a cause, and several cases are on record, and I have seen two myself, in which the administration of Fowler's Solution in the treatment of chorea has produced general peripheral neuritis. The prompt and early diagnosis of the case is essential, because then the removal of the exciting cause places the patient in a position where he can be cured.

The advances of modern surgery have enabled us to open the skull and remove new growths from the brain with comparatively little danger to life. The success of the operation depends to a great extent upon its early performance, and therefore early diagnosis and localization of a cerebral tumor enables the surgeon to do his part well. If the existence of the growth is not discovered until it has attained a large size, and when it has infiltrated the brain substance, and the patient is exhausted by long suffering, the risk of the operation is far greater and the chances of successful extirpation of the growth are smaller. The outcome of brain surgery is not invariably good enough to make one enthusiastic, for the number of tumors which are removable is comparatively small. We must remember, however, that occasionally we do get brilliant results, and that even if the growth cannot be removed, the patient seldom dies as a result of an exploratory operation, and there is always relief to pain and other distressing symptoms. If the diagnosis of brain tumor is established, and no relief is afforded by the free and judicious use of alteratives, an operation should be done at once, provided, of course, that the growth can be accurately localized. If the neoplasm is in the motor area, localization is generally simple. Knowing, as we do now, the functions of the greater part of the cerebral cortex, one should be able to fix the position of a tumor with reasonable accuracy, provided that it is not in one of the silent regions of the brain; for example, the frontal lobe.

Tumors of the spinal cord have been successfully located and operated upon. Horsley first removed a tumor of the cord in 1887 and MacEwen shortly after was successful in similar operations. Operations upon the spine are more difficult and hazardous to life than those upon the brain.

A better understanding of hysteria enables us to distinguish that disorder from organic disease, but sometimes even the elect are deceived. It often happens that organic diseases, especially tumors of the brain, have associated with them various stigmata of hysteria. Not long ago I saw in consultation a married woman of thirty years of age, in whom there were many symptoms of hysteria. She was emotional and had had mild religious melancholia for several months. Then came convulsive seizures, which seemed to be under the control of the patient when she was spoken to in a positive and authoritative way by her physician. I found, however, on examination, that there was paresis of the left arm and leg; that the leg was spastic in attempts to walk, and what was very diagnostic, that there was violent patella tendon reflex, and strong ankle clonus on the left side, while on the right these reflexes

were normal. This convinced me that there was present a tumor of the brain, and an examination of the eyes by an oculist revealed optic neuritis and choked disk, thus confirming my opinion. The convulsive attacks of the left leg and arm, with absence of face involvement, and no loss of sensation, made me locate the growth in the upper portion of the right motor area. An operation was done, and a growth springing from the dura, the size of a duck egg, and dipping down into the fissure of Rolando, was removed. Owing to an unusually thick skull and extreme vascularity of all the tissues, there was great loss of blood, and the patient unfortunately died a few hours later from hemorrhage and shock.

Neurasthenia is a disease which is still a stumbling block to many. If we regard it as a condition of malnutrition, and as a fatigue neurosis, with irritable weakness of the nervous system, we will understand it better. The manifestations of neurasthenia are manifold. They are headache, backache, general lassitude, insomnia and weakness of the digestive and sexual apparatus. Probably no one of these symptoms is more constant or gives rise to more annoyance than the digestive disorder or "nervous dyspepsia," as it is so often called. We must realize that the gastric symptoms are of two kinds, those which precede the neurasthenia for months or even years, and which may be regarded as causative, and those which arise as a result of neurasthenia, and in which the gastric indigestion is due to defective nerve force. I believe that the latter form is most common, and the only way to cure it is to cure the neurasthenia. Build up the system, repair the nerve force and renew the quality of the nerve cells, and the dyspepsia will yield to appropriate treatment and often will disappear without any special treatment. By far the most successful method of treatment in neurasthenia is the "rest treatment," and isolation is the keystone of that treatment in most cases.

The fuller understanding of nervous diseases has led to better results in their treatment. Many diseases which used to be considered the opprobria of medicine are now more or less amenable to remedies and are greatly benefited by modern methods. Take epilepsy for example: This disease, which was formerly considered insusceptible of relief, is, in many instances, greatly ameliorated by suitable methods and is sometimes apparently cured. It is not at all uncommon to see cases of epilepsy, in which long remissions varying from months to several years occur as the result of properly applied measures, both hygienic and therapeutic. The judicious and careful use of the bromides certainly keeps the attacks under control in many instances, but the remedy must be kept up continuously and its effects carefully observed. A plan of giving bromide in epilepsy, which has been recently advocated by Gilles de la Tourette, seems the most methodical and scientific yet devised. It is what is called "the adequate dosage method." This plan is based on the determination of the actual individual tolerance of each patient by watching for certain physical signs peculiar to the drug, indicating the approach of tolerance. The individual "adequate dose" thus established is maintained for a length of time sufficient to completely abolish the

hyper-excitability of the brain cortex in epilepsy, and with it all tendency to seizures. The method is well worth further study and investigation. Other diseases have been successfully treated in this way, such as migraine, Meniere's vertigo and tic douloureux.

Perhaps the greatest advance which has been made in the treatment of epilepsy has been in the general care which has been bestowed upon the unfortunate class who suffer from this disease. An effort has been made to take from the almshouses and insane asylums the indigent epileptics who have been sent to these institutions as the only resource, and colonizing them in farms and rural districts. Special institutions for the care of epileptics have been established within recent years in Europe and in different parts of this country. The first attempt at anything like establishing an institution for the special care of epileptics was made as long ago as 1773, by the Bishop of Würzburg, Germany, by providing a home in connection with the Julius Hospital; and in 1845 a separate building was erected for forty-eight patients. The most important step in the direction of a colony for epileptics, however, was taken at Laforce, France, in 1848, when John Bost, a clergyman, with the aid of his parishioners, opened a cottage for the accommodation of fifty homeless epileptic girls. The growth of the institution has been quite remarkable. In 1862 another cottage was opened for boys, and additional cottages have been added, until now there is a large village entirely occupied by epileptics. In 1867 the celebrated colony of Bethel, near Bielefeld, was founded by another minister, Pastor von Bodelschwingh. The development of this colony has been extraordinary. The number of patients there in 1897 was 1441. There were 663 women, 550 men and 228 children under fifteen years of age. During the year 1897, 250 patients were received and 109 were discharged. The entire number of patients received in the colony since its establishment until January 1, 1898 was 5028. Of these, 388 or 7.7-10% were discharged as cured; 1009 or 21% improved; 1058 as not cured and 991 or 19.1-10% died.

The examples of these institutions led to the establishment of several others in Europe, and within the past ten years similar institutions have been organized in this country. The first State farm for epileptics in this country was established in Ohio in 1893, and this institution seems to be in a flourishing condition. In 1894 the State of New York appropriated \$115,000 for the purchase of a farm in the Genesee Valley, which had formerly been occupied by a Shaker community, to be used for the establishment of a Colony for Epileptics. This is a splendid tract of land in the most beautiful and picturesque part of New York State. The colony consists of about 1900 acres, most of which is fertile and arable land. It was opened in January, 1896, and it now contains between five and six hundred patients. These patients are employed in working on the farm, caring for live stock and performing all manner of manual labor. In the winter they are employed in the workshops and are kept usefully occupied.

In several other states there are similar institutions. In the State of Pennsylvania there is a col-

ony farm which has been organized and equipped with fine buildings by private enterprise. This institution was opened in February, 1868, and is conducted on the same principles as the Craige Colony Farm in New York. In other states efforts are being made to establish similar institutions. My friend, Dr. Drewry, of the Central State Asylum of Virginia, has been greatly interested in this subject, and has succeeded in interesting the Legislature for the establishment of a colony farm for epileptics. It is to be hoped that in every state in the country there will be similar institutions established. The results of the care and treatment of epileptics in institutions like these mentioned are most encouraging. The number of fits lessens to an extraordinary degree, simply as a result of the carefully regulated life and close attention to hygienic rules, and the amount of drugs which is required is reduced to a minimum.

I might go on indefinitely citing cases to prove my original statement that early recognition of nervous diseases is essential to their successful treatment, but it would exhaust your already sorely taxed patience. I cannot refrain, however, from giving one more illustration, and that is myxedema and sporadic cretinism. Osler, in a recent paper, says: "It is astonishing with how little reading a doctor can practice medicine, but it is astonishing how badly he can do it. Not three months ago, a physician living within an hour's ride of the Surgeon General's Library, brought his little girl, aged 12, to see me. The diagnosis of infantile myxedema required only half a glance. In placid contentment he had been practicing for twenty years in Sleepy Hollow, and not even when his own flesh and blood was touched did he rise from an apathy as deep as Rip Van Winkle's sleep. He had never heard of myxedema or cretinism." There is nothing in modern medicine which is more marvelous than the influence of thyroid therapy in myxedema. A flaccid, stunted dwarf, with pendulous abdomen, bowed legs and puffy and bloated countenance, and a tongue so large that it cannot be retained in the mouth, and possessing no more sense than an idiot, after a few months of thyroid feeding becomes a straight, active and intelligent being. The dropical puffiness disappears, the tongue is held in the mouth, and what is most remarkable, several inches are often added to the height even after the age of thirty years.

And now, gentlemen, I trust from what I have said, that I have made it clear of how great importance a more extended study of nervous diseases would be for the general practitioner and family doctor. The next question is, what facilities and opportunities are available for this study? It seems to me that every doctor throughout the country ought to refresh his mind by taking, from time to time, a course in special subjects. He should go to the larger cities, where there are great opportunities for the study of all specialties, particularly nervous diseases. It is only by the study of disease, by the investigation of large groups of cases, that the best results can be obtained. In the great cities like New York, Chicago, Philadelphia and Baltimore, there are many post-graduate schools of medicine, and here neurology can be best studied in a

comparatively short time. Every physician should use his influence for promoting the teaching of nervous diseases in the medical schools in his own state. He should insist that a special course on neurology should be given, and more particularly that Chairs of clinical neurology should be established, so that students will have the opportunity of seeing and personally studying the various forms of nervous diseases. The study of the anatomy of the nervous system is a necessary preparation to the clinical observation of neurology, and there is nothing of greater value than the work done in the laboratory devoted to the pathology of the nervous system. The foundation must be first laid upon a thorough comprehension of the normal histology of the nervous system: then the student will be able to appreciate the pathological changes which take place, and with this preparation the study and treatment of nervous diseases becomes a matter of actual pleasure and deep interest to the general practitioner.

THE MOSQUITO AN INSIGNIFICANT FACTOR IN THE PROPAGATION OF YELLOW FEVER.

By JOHN H. PURNELL, M. D.,

of Vicksburg, Miss.

State Health Officer in charge of the Epidemics at Edwards, Miss., 1897 and Jackson, Miss., 1898.

Since the first observance of yellow fever there have been controversies constantly occurring relative to its mode of transmission and propagation; but the fomites theory has always been maintained in the lay, as well as medical world. La Roche made a most masterly onslaught on this theory, and dealt a staggering blow, but practical experience in the epidemical field by men of observation, restored its equilibrium, and until the meeting of the Pan-American Medical Congress in Havana, Cuba, in February last, its acceptance was universal, with possibly a few dissenting voices. The sudden announcement that the whole Medical World was entirely wrong, and had been pursuing an "Ignis Fatuus" was startling indeed; and the further claim that the mosquito, alone and unaided, was solely responsible for the distress, desolation and death, resulting from epidemics, seemed a little less than marvelous.

Many—and some in high places—in the Medical World, accepted the new dictum without a word of protest, and have already advised the abandonment of the protective measures now in vogue against the introduction of the yellow fever germ, and declare them to be unnecessary and unscientific. Others cling to the old customs, and marvel at the complete annihilation of the accepted theories of years, by a series of experiments conducted in a camp, on eighteen or twenty subjects, in the winter season, when the virulence of the yellow fever germ is on the wane.

Ordinarily, in mid-summer, we can control an epidemic if the people can be moved to a camp; Fortress Monroe, 1899, for example. As to the soiled material which was introduced into the little cabin being sufficient upon which to base an absolute conclusion, is concerned, I point to the fact that in nearly every epidemic analogous instances

may be found—La Roche teems with them—and cases of fever do not occur simply because the *infect* is absent. Stench and filth are incapable of producing infection. What does, is shrouded in mystery. The germs, as they are discharged from the human body, do not at first seem capable of infecting, but must remain for a time in an undisturbed atmospheric area which is suitable to their evolution before infection is possible. Unless the proper meteorological conditions prevail, the poison seems to be inert.

An illustration of the conditions not being present, is found in Keating's History of the Epidemic of 1878, in speaking of Camp Joe Williams, which was located near Memphis, and was peopled by a thousand or more refugees from the city. A number of persons who had become infected before leaving the city developed the disease after reaching the camp, but from such cases there was no spread. Surgeon R. B. Nall, who was in charge of the camp, says: "The remarkable and favorable feature of Camp Joe Williams, was that the disease did not spread amongst its inhabitants, nor did those who visited the camp from the surrounding country contract the disease. * * * *

"On the arrival of the refugees, every article of bedding and clothing which favored the propagation of the disease was destroyed by fire. * * *

Five of the eight male nurses employed in the hospital, after nursing for three or four weeks fifteen or twenty patients in all stages of the fever, thinking themselves proof against the disease, went to the city to offer themselves to the Howard Association as nurses because of the higher prices paid. They found the sick bountifully supplied with nurses from elsewhere, and were unable to obtain positions, and returned to camp. Four of these men died in the hospital in which they had nursed—the fifth was found dead between the city and camp. The other three nurses did not visit the city, but remained in the hospital during the epidemic (seventy-two days), nursed and buried their comrades, but were not attacked themselves."

The foregoing is a plain unembellished statement of a reputable physician, and contains several points of interest in connection with the recent investigations carried on in Cuba.

1st: If the bedding and clothing in the hospital at Camp Joe Williams during the *summer* weather did not become infected, is there not good reason to suppose that the material taken from Las Animas Hospital and Quemados in November and December escaped likewise? The non-immune physicians and nurses who attended yellow fever patients in Las Animas in 1899 failed to develop the disease while there, but did develop it afterwards from an infected center. (Information from Surgeon H. R. Carter)

2nd: All bedding and clothing coming from the infected city was burned, and while yellow fever cases developed in those who had become infected before leaving the city, none occurred in any other—is it not reasonable to suppose that the precautionary measures were responsible for the immunity?

3d: Since it is known that mosquitoes plentifully

abound around the suburbs, as well as in the City of Memphis, and as no measures were adopted looking to the destruction of the pests, is it reasonable to suppose they would have confined their stings to the inhabitants of the city and permitted the camp to remain unmolested?

The mosquito's capability of conveying the yellow fever poison from man to man seems proven—that is—twelve days after its having been infected, its sting may produce yellow fever in the human. From the clinical histories of the cases reported as resulting from the mosquito stings, the impression is gained that the attacks were extremely mild. Is it not possible that after passing through the organism of the mosquito, the poison is so attenuated that immunity may thus be gained with but a small risk to life? Be that as it may, it is agreed that the mosquito, acting as a host, produces yellow fever, and that its supply of poison is obtained by stinging a person suffering with the disease. Where did the primary infection come from? If from a source independent of the mosquito—then it is reasonable to suppose that it may still be so obtained. If the mosquito is infected in other ways, than by stinging a yellow fever subject, then we should have epidemics with the advent of the mosquitoes. It is assumed, however, that the mosquito is infected solely from cases of yellow fever, and it is necessary that twelve days should elapse after the contaminating sting before infection is possible. Such being a fact, any cases developing earlier than the twelfth day must depend on some other agent. The history of the beginning of the epidemic at Edwards, Miss., in 1897, furnishes an illustration of such a condition.

On August 8th Mrs. A. returned to her home near Edwards from a visit to her daughter in Ocean Springs, Miss. At the time of her visit a sickness was prevailing, the nature of which had not then been determined, but shortly afterwards it was declared to be yellow fever; upon reaching home Mrs. A. was taken ill, and within two weeks her entire family of eight suffered attacks similar to her own. On August 25th, Mr. C., who resided in the neighborhood, visited the house, and on the 28th he visited the town of Edwards, and while there he was taken ill at the residence of his father-in-law, Col. M., where he remained until his death, which occurred on September 6th. He was buried on September 7th. On the night of Sept. 8th, Mrs. M. was taken ill. On Sept. 9th, midday, Col. M. was taken ill, and the evening of the same day, a young son of Col. M. also sickened. These cases were quickly followed by a number of others, occurring in persons who attended the funeral, amongst the number being two from a distance who are reported in Surgeon H. R. Carter's article on "The Period of Incubation of Yellow Fever." (*Medical Record*, March 9, 1901.) His report was as follows:

1st. L. M. W. went from Clinton to C.'s funeral, at Edwards, Miss., Sept. 7th, 1897; arrived about 11.30 A. M., and left that afternoon. She developed Yellow Fever at Clinton, Sept. 10th, at night.

2nd. M. C. went to C.'s funeral at Edwards, Miss., Sept. 7th, 11.30 A. M., and left that afternoon for Nitta Yuma, Miss., and developed Yellow Fever, Sept. 11th, night.

There was no question as to the C. case being the center of infection. What, then, was the agent of distribution? If the mosquito conveyed the poison,

the sting of contamination must have occurred on or after August 28th. The first case noted was Mrs. M., taken ill on the night of Sept. 8th, eleven days from the beginning of C's illness, and since the period of incubation seems to be about three days, then there remain only eight days from the first possible exposure.

Case 2nd and 3d gives us nine days, while cases reported by Surgeon Carter were only exposed once—ten days after primary case was taken sick.

If conclusion No. 3 of investigator is correct, then these cases could not possibly have developed through the sting of the mosquito. The rapidity with which cases developed after the 15th of September was truly marvelous. The population was composed of 325 whites and about 600 colored, and by the 1st of November—60 days after the first case—there had occurred 290 white, and 427 negro cases. Is it reasonable to suppose that each case was the result of a sting delivered by a mosquito who had stung a case of yellow fever twelve days previously? In this connection, dwell for a moment on the Epidemic of 1878, extending from the Gulf of Mexico, throughout the Mississippi Valley to Gallipolis, Ohio, and resulting in 72,000 cases, with 16,000 deaths. Is it reasonable to suppose it was accomplished by the Mosquito?

In yellow fever literature quite a number of instances are recorded where the introduction of infection is attributed to fomites, and I believe those who reported the instances were impressed with the correctness and authenticity of the circumstances.

The following case fell under my observation:

On Sept. 14th, 1897, Mr. and Mrs. B. refuged to their home seven miles from Edwards, Miss. A number of people were in the house at the time of their arrival, but all left with the exception of Mr. and Mrs. H., (daughter and son-in-law of Mr. and Mrs. B.) and three servants. Mr. B. developed yellow fever on September 15th and died on the 17th. He was buried on the same day and everything was destroyed that had been in the room. The room was disinfected and sealed up. The portion of the house in which the case occurred was separated from the other rooms by a twelve foot hall in which sulphur was kept burning for two weeks. Mrs. B. had all of her clothing destroyed with the exception of a cashmere shawl, and this she was desirous of keeping; so it was placed in an upstairs room close to the eaves. On October 5th, thinking all danger of a recurrence of the disease past, preparations were made for the return of the family. Mr. H. visited the upstairs room and finding the shawl, threw it down stairs and called to some one to remove it out-doors. His wife responded and as she started out, met her mother, who attempted to rescue her property. Further than this I was not told, but two days after the episode, Mrs. H. developed yellow fever, followed by Mr. H. one day later, and Mrs. B. developed a case on the fourth day. Ten days subsequently two of the servants suffered attacks, presumably from a second infection of the house.

In Dr. Matas' article in the October, 1897, issue of the *New Orleans Medical and Surgical Journal*, he quotes an illustration of conveyance by fomites. The facts, he says, were furnished by Dr. Shannon, of Ocean Springs, Miss., in a letter to Dr. Bemiss:

On the 14th of October, 1883, Maj. J. B. D. died of yellow fever in Ocean Springs. I moved the family to a healthy locality where you saw Miss B., not allowing them to take any article from the room where the husband and father had died. The children applied to me for a lock of their father's hair, which I refused, but the older daughter, now dead, prevailed upon the nurse to give it to her. She placed it in an old envelop that had been torn

open at the end, and carefully folded the torn end down, thus practically sealing it, and laid it away among other old letters. On Sunday, the 4th of November, at 12.30 P. M., she brought this envelope out upon the gallery and opened it for the first time to examine the lock of hair, and to show it to her aunt, Miss S., who was visiting her, and upon inhaling the concentrated poison confined in the envelope and emanating from the hair, exclaimed: "O! what a peculiar smell." She then handed the envelope to Miss S., who unconscious of danger, also inhaled the "messenger of death" with a similar exclamation. When Mrs. B., who was standing near, reached out her hand for the envelope, but was prevented by the entreaties of a fretful child to be taken up in arms. This gave time for reflection, and she admonished the young ladies of the possible danger. The envelop was carefully folded and with its fatal contents replaced in the drawer, where it has been since the 14th of October. This drawer has been almost daily opened. On the following Saturday, November 10th, at 9 P. M., Miss S. was taken sick with a chill, and Miss B. at about 2 A. M., some five hours later, the period of incubation being less than seven days in both cases. No other person handled the fatal envelope or in any way came in contact with it, and there is after the most careful inquiry, no suspicion of any other source of infection in these two cases. Miss S. died on November 14th; Miss B. on November 16th.

In this case there was an interval of twenty-seven days between the death of a single case of yellow fever and the development of a second. It is presumable that in the removal from the house the mosquitoes were left behind. If, however, one or two had been carried from the house, it would have been a strange coincidence indeed for them to have selected these two young ladies, who had been in contact with the hair, for victims.

Dr. J. A. K. Birchett, State Health Officer, at Taylor, and Orwood, Miss., during the 1898 epidemic, reports the two following cases of infection by fomites as having fallen under his observation:

1st: "On September 7th, I visited the Gray House midway between Taylor and Orwood, and found Mr. McC. confined to his bed with an attack of yellow fever. About September 15th he packed the clothing worn at the Gray House in a valise and proceeded to his home, about ten or twelve miles distant in an isolated spot. On October 13th his wife removed the articles from the valise and hung them out for an airing. On October 16th, at 3 P. M., she sickened with an attack of yellow fever."

2nd. "Miss A. B. attended the funerals of Dr. G. and H. W., on August 10th and 11th, at which time she was clad in a woolen dress, which she took off and placed away in a closet on her return home. She was exposed to a case of yellow fever at 7 P. M., August 25th, which was positively the last exposure to yellow fever. About September 20th she was renovating the house and removed the clothing (the woolen dress amongst other things) from the closet to air them. She was taken with yellow fever at 7 P. M., September 25th. The isolation of these premises had been perfect, it being dangerous to attempt an approach to the house, as my driver can testify; he was shot while attempting to cross a portion of the place."

In the History of the Yellow Fever Epidemic in 1878, by J. M. Keating, are mentioned a good many instances of fomites infection, several of which will bear relation:

1st.—At a meeting of the Davidson Co. Medical Association, Dr. Drake, of Nashville, reported the following case:

"At Jacksonville, Tenn., in 1878, a gentleman returned from Memphis, and upon reaching home hung his clothes in a wardrobe. After several days his wife took the clothing out. We would suppose that in a close hot room the poison would multiply itself in this time until the air would be heavy with it; and so it seemed in this case, for the lady took the yellow fever and died, followed in due

time by the rest of the family. The husband developed the disease only when confined to the house ministering unto the sick."

2nd.—Dr. T. J. Heard, of Galveston, Texas, is quoted as follows:

"About December 1st, 1864, Mrs. Vincent, sister of Ex-Lieut. Governor Anderson, fled from Houston on account of yellow fever. A negro left behind took the disease, and as there was great lack of blankets, an old carpet was used instead. Six weeks afterwards Mrs. Vincent returned, and going in the garret took the carpet out to air it. Four days after this she had a most violent attack."

3rd.—Dr. Jacob S. West, of Texas, is quoted as reporting two instances where coffee introduced infection. Both occurred in 1867, and are related as follows:

"At Liberty, Texas, a sack of coffee landed two miles below town from the steamboat Ruthven, which coming from Galveston, was refused permission to land at the wharf. This sack was taken on a dray to Liberty. All who shared the coffee were stricken with fever, which spread with disastrous effects."

"The second case was that of a sack of coffee which was hauled fifteen miles in an open wagon from Corpus Christi, where fever prevailed, to a point near Meansville, where it was divided among the purchasers. No one of them escaped and many of them died; but those who did not so share, singularly enough, escaped."

4th.—Keating reports on the source of infection at Covington, Tenn., as follows:

"The only person who had the fever at Covington, Tenn., in 1878, was the Post Master, who received and opened a heavy mail that had been detained in the Memphis Post Office for some time. In three days he died of yellow fever."

The foregoing reported instances of fomites conveyance, I think, are sufficiently authentic to demand a careful consideration before discarding the theory that has been uppermost in medical minds during the past century. * * * At the present time few, if any, medical men seriously believe in the origin of yellow fever in the States, but a recrudescence has been occasionally noted. It can scarcely be conceived that the mosquito could harbor the germ for such a time as marks the period between the last appearance of the disease and its recurrence. Consider the epidemics of 1878 and '79 in Memphis. An extremely cold weather followed the '78 epidemic, and in the early part of July, 1879, cases appeared in several portions of the city simultaneously, and in different strata of society, proving that each case developed independently. On July 9th the Mulbrannon case was reported from the eastern part of the city; on the 10th Judge Ray's family (several cases) was reported from the western, and the Tobin family was reported from the northern part. After ten days or two weeks had elapsed an epidemic prevailed.

Edwards, Miss., is another illustration of a recrudescence—a few cases occurring in September, 1868, following the epidemic of the year before. The recurrence of the disease on the Plymouth is a striking illustration of a recrudescence. The reappearance of yellow fever on her as the tropical seas were approached, after disinfection and a subjection to freezing weather for three or four months, certainly indicates that the morbid principles of the disease were hidden away in some of the nooks or niches of the hold. The history of the old "Jamestown," in 1858, is even a stronger argument against the

mosquito than the "Plymouth." It is related by Dr. Nelson in the Twentieth Century Practice as follows:

"It (the fever) duly appeared on the United States Steamship "Jamestown," on which as many as eighty officers and men died. A crew took her North to San Francisco. She was kept in the Northern Pacific for a period of two years, when she was ordered to the Hawaiian Islands. Upon getting into the Warm Belt, yellow fever reappeared. Had she been sent to a yellow fever port, and had the disease appeared, the claim might have been made, and with great propriety, that the vessel had been infected *de novo*; but this is clear and emphatic evidence to the student of yellow fever of the vitality of the poison of the disease. In Hawaii yellow fever is unknown."

The following is from the same author:

"I will cite another case illustrating the vitality of the poison of the disease. A small vessel in the tropics had had yellow fever on board. She was sent North in the fall of the year and sunk in a northern river. When the winter came on the vessel was frozen in, or submerged in icy cold water all winter. In the spring she was pumped out and raised, after a time put in commission, and sent again to a warm climate. Upon getting into the warm belt, and before making a port, the disease reappeared."

It does not require a very close scrutiny of the foregoing to cause us to conclude that there must have been some other agency at work than the "Culex Fasciatus." From a recrudescence of the disease, we will pass to another phase. If the absolute absence of mosquitoes, would prove the development of a case of yellow fever dependent upon some other agency, then the development of a case a week or more (I say a week because the period of incubation is placed at from 41 hours to 5 days) after the termination of a possibly infected mosquito's life, would also fix the agency elsewhere. Frequently have been found cases developing on ships one or two months after having sailed from an infected port; and such case or cases are usually associated with the disturbance of the cargo, ballast or something on shipboard. In the Medical and Surgical Memoirs of Dr. Joseph Jones is to be found the following illustration:

"The bark "Excelsior" sailed from Rio on May 10th, 1880, with a cargo of 3600 sacks of coffee. Crew consisted of three officers and nine men. They arrived at Mississippi Quarantine Station on June 24th, having been on the voyage about 46 days. She was released from quarantine and reached New Orleans on July 5th. No case of fever occurred on the voyage or at the quarantine station. About sixty hours after reaching New Orleans, and after discharging her cargo, James Kinney, one of her crew, was attacked with yellow fever and died in the Touro Infirmary, after throwing up black vomit. The first case was not reported to the Board of Health until July 10th, when the crew were mustered and ordered to stay on board. The bark was forcibly returned to the Mississippi Quarantine Station by order of the Board of Health. Cases of yellow fever occurred on board of the Excelsior on the 12th, 13th and 14th of July and deaths occurred in the Quarantine Hospital on the 17th and 18th of July."

In the article by Surgeon H. R. Carter, appearing in the April issue of the Philadelphia Medical Journal, appeared the following instances of long retained infection:

"British ship Avon, rock ballast, 22 in crew, all except four non immune, left Rio Janeiro April 20th, 1900. All well in port and en route until the thirty-ninth day out, when entering Ship Island, a boy sickened with yellow fever and died; one other man, a quarantine employee, who assisted in cleaning up the room where the boy was treated aboard ship, sickened fourteen days after."

"British ship Curlew, from Rio, in rock ballast, crew mainly non immune. All well in port en route, and on arrival. After cleaning ship, one man sickened with yellow fever, 64 days from Rio."

"British ship Chippewa, from Rio, rock ballast; all save 3 men and master non immune to yellow fever. All well in port, en route and on arrival. After cleaning ship, one man sickened with yellow fever, 68 days from Rio."

It seems to me to be utterly impossible to reconcile the mosquito theory with any of the above recitals; while the life of the mosquito has not been determined, the shortest period mentioned above certainly exceeds a mosquito's existence.

Among the many sanitary measures adopted, looking to the control of yellow fever epidemics, and to the complete eradication of the disease, no exertions were ever directed toward the mosquito's extermination, until the onslaught was made on the hatcheries around the suburbs of Havana within the last four months. Other islands besides Cuba, in the same vicinity, suffered from the ravages of yellow fever, and succeeded in freeing themselves from it, but not by the use of coal oil, insect powder and mosquito bars! Several instances, within the last few years, in the South have occurred where yellow fever has been completely stamped out, without, so far as is known, the killing of a mosquito. In 1899 the disease appeared in the Soldiers' Home at Fortress Monroe, and by establishing camps, and prosecuting sanitary measures, the epidemic was promptly checked. No effort was directed toward mosquito extermination, nor was there in the control of the fever at McHenry, Miss., by the Marine Hospital Service and the Mississippi State Board of Health.

The prompt measures adopted by the Mississippi State Board of Health, at Clinton, Miss., in 1897, confined the fever to one portion of the town, but their method did not molest the mosquito. * * * If the combating of yellow fever has been accomplished by controlling and destroying other agents than the mosquito—under conditions where the mosquito has been absolutely ignored and permitted to pursue his own sweet way, then it seems the mosquito has not been proven guilty of being the sole conveyor of the yellow fever germ, and we will do well to continue our search before crying "Eureka."

In presenting the foregoing data, I am aware that many will criticize it as being imperfectly exact. It is not offered, however, as conclusions based upon a scientific experimental research, but as facts as observed and related by men laboring in the field of yellow fever, which were not told for the purpose of proving a theory, but simply to chronicle happenings as they occurred, and as such demand attention. From my own experience, I am forced to the conclusion that the mosquito has been, and will continue to be, but a limited factor in the spread of yellow fever, and I have no hesitancy in predicting that future observation and study will convince the profession that fomites cannot be ignored.

TYPHOID FEVER WITH PERFORATION OF THE COLON AND GALL-BLADDER; OPERATION; DEATH; AUTOPSY.

By HERMAN B. ALLYN, M. D.,

of Philadelphia.

Instructor in Physical Diagnosis, University of Pennsylvania Clinical Professor of Medicine, Woman's Medical College, Physician to the Philadelphia Hospital.

Statistics that have been compiled in recent years show that it is possible to reduce the mortality from typhoid fever to seven per cent. Such a result can be achieved only in hospitals which are exceptionally well conducted; I might say, only in hospitals in which the treatment of typhoid fever is given special attention. Osler, from the Johns Hopkins Hospital, Baltimore; J. C. Wilson, from the German Hospital, Philadelphia; and F. E. Hare, from the Brisbane Hospital, Queensland, Australia, have reported a mortality ranging from seven to eight per cent. in large series of cases, all treated by the Brand method. We may regard seven per cent., therefore, as the best that can be achieved by the medical treatment of typhoid fever. It is well known that in most hospitals the mortality is higher, ranging from eight to eighteen per cent., depending largely upon the class of cases treated. The problem now is to reduce still further the number of deaths from this scourge of modern civilized life. Osler states that among 100 fatal cases, 50 die of the progressive asthenia; 30 of perforation, and 20 of other complications. Of 63 deaths in the first ten years of the work of the Johns Hopkins Hospital, nearly one-third were due to perforation. In 4,680 cases collected by Fitz, the mortality from perforation was 6.58 per cent. The mortality from progressive asthenia may be overcome by early recognition of the disease, prompt confinement to bed, and by the most zealous care of the patient throughout his illness, particularly with reference to feeding and to saving the patient's strength. The mortality from perforation must be overcome by early recognition of the accident and by immediate operation. This subject has recently secured the attention of some of our most skilful clinicians and surgeons: R. H. Fitz, W. W. Keen, William Osler, J. M. T. Finney, and H. W. Cushing. Finney has collected 112 cases of perforating typhoid ulcer which were operated on; 23 recovered, 20 per cent. This means that the lives of 23 patients have been saved by surgical interference, for practically no case of perforation recovers without operation. The following case is reported as a contribution to the statistics of perforating typhoid ulcer. The special difficulties in diagnosis which were encountered at the time of operation make the case of unusual interest:

W. C., colored, 19 years old, a native of Virginia, laborer by occupation, was admitted to the Philadelphia Hospital June 16th, 1901, complaining of pain in the left chest, headache, and pain in the abdomen; he was mildly delirious. The family and previous history of the patient could not be elicited from the patient owing to his delirium. From his appearance he was thought to be in the second week of typhoid fever. The ambulance history says: "The attack began six days ago with severe headache, and some pain in the stomach. There were no chills or chilly feelings. He says he was very hot. At present the headache is not so severe, but he complains of pain in the back and left side which is increased by deep inspiration. The bowels are constipated, but laxatives produced thin greenish

stools. The tongue is extremely coated and furrowed, red at tip. There is tenderness in the right iliac fossa. There is a dry hacking cough. No nose bleed. Pulse 128, tremulous; respiration 40, but quiet.

The patient was a mulatto, apparently about of age, fairly well nourished. The pupils were equal, slightly dilated, reacted to light and accommodation. The tongue was coated on the dorsum with a dry crust, the edges were indented by the teeth. The appetite was poor; the bowels were constipated up to admission, or until laxatives were given. The pulse was regular, soft, small, slightly tremulous. Respiration was increased in frequency and largely abdominal. The heart was normal in size, the sounds at the apex strong, the aortic and pulmonary sounds accentuated. There were no murmurs. The right lung was normal; the left lower lobe was dull on percussion, with bronchial breathing. The abdomen was distended and tympanitic, but there was neither gurgling nor tenderness. The spleen was not demonstrably enlarged. The liver was normal in size. There were a few pigmented spots on the chest. The extremities were negative.

After admission the patient's delirium at first increased. He lay with his eyes open, and while he could be roused to talk a little, he did not answer questions intelligently. He muttered to himself at times.

June 18th. Gurgling in the right iliac fossa. Left lung posteriorly shows bronchophony and tubular breathing. The patient is delirious and very nervous. General condition fair.

June 20th. Delirium greater. Patient has not slept since admission. The signs of consolidation at left base show improvement. In the evening the patient was wildly delirious; temperature 104. Saline solution was given by hypodermoclysis by Dr. Behrend, with much benefit to the patient. The urine contained albumin and numerous granular casts. Diazo reaction positive. The Widal reaction was also obtained.

June 22d. Patient has had some sleep and seems better. Delirium no longer present. Kernig's sign absent. He talks and mutters in sleep. The tympany is less; the abdomen flaccid. Tongue is fissured and thickly coated with white fur.

June 24th. Tympanites again marked this morning; abdomen drum like; liver comes to costal margin; spleen apparently normal. Bowels moved three times. In the evening the abdomen became much softer.

June 25th. The temperature dropped to 97° after a tub bath. The patient complained of pain in the abdomen. He was very uncomfortable in the night. After another bath the temperature dropped to 98°. At 10.30 P. M. the temperature was 104.1° F. The right side of the lower jaw was swollen. The patient was very uncomfortable, complaining of pain in the abdomen. The temperature without a bath dropped steadily from 11.30 P. M. to 2.30 A. M. (June 26th) when it reached 97°. There was a profuse sweat. Dr. Behrend, the resident physician in charge, saw the patient at this time. The abdomen was very hard. The liver was pushed up about one and a half inch above the costal border. There was pain in the right iliac fossa, and the patient was in collapse. The patient was transferred to the operating ward and Dr. J. Chalmers Da Costa performed a laparotomy about 4 A. M. He found peritonitis and considerable straw colored fluid in the abdomen, but no perforation nor any thickening of the coat. A few dark areas were found on the surface of the gut ranging from a pin-head to a small pea in size. The patient lived three days after the operation. The temperature became more remittent in type and at death was 107°.

The autopsy was performed the following day by Dr. W. F. Hendrickson. The following is an abstract of the autopsy notes: Pathological diagnosis: Typhoid ulceration of intestines; general fibrinous peritonitis; enlarged mesenteric lymph nodes; acute splenic tumor; acute double lobar pneumonia; fatty degeneration of liver; acute cholecystitis; parenchymatous degeneration of kidneys; chronic pleurisy; aortic sclerosis. About 250-300 cc. of dark brown fluid, of fecal odor, was found in dependent portions and pelvis. Adhesions were found between gall-bladder and hepatic flexure of colon. No escape of intestinal contents found at this point. Separation

of adhesions reveals opening in the gall-bladder 1 cm. in diameter communicating with a small opening into the gut 5 mm. in diameter. Entire surface of gall-bladder considerably injected. About the opening in the intestinal wall corresponding to opening in gall-bladder at this point are a few superficial areas of ulceration of small size.

The location of the perforation in this case is the feature of special interest. At the time of operation peritonitis existed, and fluid was found in the abdomen. Dr. DaCosta examined several feet of the intestine in the neighborhood of the ileocecal valve, and while the intestine was found intensely congested, neither perforation nor any area of thickening of the coat was found. The gall-bladder region was examined digitally, but nothing suspicious detected. Even at the autopsy the pathologist did not suspect perforation in the colon beneath the gall-bladder, and it was discovered only after adhesions between the two organs had been separated. Dr. Hendrickson concluded that ulceration of the colon had been primary, and that of the gall-bladder secondary. The presence in the abdominal cavity of fluid of fecal odor justifies this belief. The gall-bladder was, however, empty and the seat of inflammation and ulceration. Typhoid bacilli were obtained from a culture from the mesenteric glands.

Of the 112 cases operated on for perforating typhoid ulcer of the intestines, collected by Finney, in not one was the large intestine involved. Almost always the perforation was in a thickened and inflamed Peyer's patch in the ileum, varying from 2 cm. to 1 meter above the ileocecal valve. In Fitz's tables, however, in 167 cases the large intestine was the seat of perforation in 20; while in Hawkins' series of 72 cases, the perforation was found in the ileum in 61, in the cecum in 3, in the appendix in 3, and in the colon in 5.

Perforation generally occurs in severe cases during the second or third week, and in patients who have or have had diarrhea, tympany or hemorrhage. The symptoms indicating perforation of the intestine are pain, nausea and vomiting, collapse, fall of temperature, diminution or obliteration of liver flatness, leukocytosis. According to Finney's analysis of 112 cases, pain occurred in 58, nausea and vomiting in 26, collapse in 15; a fall of temperature in 14. In 9 cases the symptoms were not marked and came on gradually. In 5 cases only was absence of liver dulness noted. In 9 cases a wrong diagnosis was made. In our patient the symptoms were pain in the abdomen, a fall in temperature, accompanied by a profuse sweat, and later a state of collapse. The abdomen was rigid and the area of liver flatness in midclavicular line diminished. The blood was not examined for leukocytosis. It is noteworthy that during the entire day of June 25th the tub baths produced a much greater effect on the temperature than usual, reducing it twice to or below normal, and that the patient was very uncomfortable. Unfortunately, the leukocytes were not counted. Cushing thinks a sudden decrease in the number of leukocytes a worse sign than an increase. Perforation probably occurred about 11.30 P. M., June 25th. The operation therefore was about 4½ hours after perforation.

Typhoid affections of the gall-bladder are not

very uncommon. Mason and Osler have written valuable papers on the subject. Westcott (Keen's monograph) has tabulated 74 cases; 30 resulted in perforation; 4 were operated on, and of these 3 recovered. The remaining 27 died. In 19 of the cases the onset was in the third week or later. Seven had gall-stones, and in 16 none indicating cholecystitis were found. In our case there were no symptoms.

POST-TYPHOID CASE IN WHICH DURING FOUR MONTHS THE FOLLOWING OPERATIONS WERE PERFORMED.

1. Fixation of a mobile painful kidney with subcapsular hemorrhagic effusion.
2. Removal of a large gastric ulcer by a new method and pyloroplasty.
3. Opening of a large rectal abscess.
4. Appendectomy by electric forceps and invagination of portion of the cecum.

By ANDREW J. DOWNES, A. M., M. D.,

of Philadelphia.

Gynecologist to St. Mary's Hospital.

Miss J. S., aged 27 years, Norwegian, had been healthy until the fall of 1897, when she was ill for thirteen weeks with a severe attack of typhoid fever. While convalescing she began to have pain in the left side and back, generally dull, occasionally acute and accompanied with headache. Pain in the left renal region and headache have been constant ever since. A year after typhoid she had very severe cutting pain in this region, was in bed two weeks and was given several hypodermics of morphia. She has occasionally had several severe acute exacerbations since but has never at any time when conscious been entirely free from pain in the left side. The pain shoots down from the left renal region along the course of the left ureter. At times urine becomes scanty along the course of the left ureter. At times urine becomes scanty with increase in renal pain, at times it flows freely and the pain improves. The scanty flow continues for two or three days at a time and is attended with the sensation of swelling of the side. The feeling of distention and pain abates with the establishment of the urinary flow. Occasionally vomiting was not very noticeable until a year after the typhoid, when it occurred not less than every two or three days. In the spring of 1899 the gastric symptoms had so increased that vomiting was constant and always followed the ingestion of food or liquids. On many occasions the vomit was bloody. A few severe hemorrhages occurred. There was pain slightly to the right of the mid-epigastrium immediately aggravated when anything was swallowed. Vomiting increased the pain in the stomach and so the left renal pain. The patient was in the Methodist Episcopal Hospital for nine weeks during the summer of 1899. She was vomiting constantly and had one very severe gastric hemorrhage. Under lavage, milk diet and medicine there was some improvement. She was out of the hospital five weeks when she was admitted to the surgical wards of the German Hospital, suffering with acute abdominal pain in the region of the stomach, duodenum and lower right quadrant. She became very tympanitic, had severe and constant pain, had high fever and delirium, constantly vomited, her abdomen was covered

with ice bags and she was considered inoperable. Nothing was given by the mouth for the first six weeks. She had several gastric hemorrhages. She rallied from this attack and was able to leave the hospital January 3d, 1900, after a stay of thirteen weeks.

She was admitted to St. Mary's Hospital, December 4th, 1900. Her gastric symptoms as above detailed, which had predominated for two years, had during the last two months been overshadowed by the renal, although she had constantly vomited all but enough to keep her living. Examination revealed a tangible left-kidney, exceedingly tender on manipulation. By pressure on it pain shoots down the course of the ureter. The stomach is tender to the right of the midline. The pain in this region seems to extend as far as the head of the cecum. There is slight puffiness of the eyelids and the feet and legs are swollen. There is palpitation of the heart and nervousness. The urine is scanty. December 5th, the day after admission, my separate urines siphon was used for one hour, obtaining very little from either kidney but a little more from the right. The right urine was clear, amber, acid, containing two per cent. urea, a trace of albumen, hyaline casts, and no uric acid. The left urine was pale, cloudy, acid, contained one and one-quarter per cent. urea, a few pus cells, hyaline casts, kidney epithelial cells and uric acid.

Urine passed in 24 hours:

December 7 to December 84 oz.
" 8 " " 94½ oz.
" 9 " " 109½ oz.

Nitroglycerine hypodermically (1-100 gr. every 3 hrs.) and normal salt solution (6 oz. every 6 hrs. by rectum) were begun December ninth and the urine gradually increased in amount so that by December 13th it was thirty-eight ounces in twenty-four hours, was clear and contained no albumen or casts. The pain in the kidney, however, persisted.

Operation, December 14th, 1900. Ether anesthesia, incision downward and slightly forward from the end of the twelfth rib. The kidney appeared in the lower end of the incision and descended quite below its normal position. The fatty capsule was absent, its transparent membrane replacing it. This was incised and the kidney brought out of the wound. The capsule was loose and separated from the kidney structure by a fluid which on section of the capsule was found to be fully a half-ounce in quantity, blood-stained and of a urinous odor. The capsule was entirely free from the kidney to its hilum. The middle two-thirds of the kidney were mottled, whitish and soft; the poles were firm and of proper color. The kidney was explored to the pelvis by needling but no concretions detected. The capsule was split its entire length, reflected back and the kidney suspended by the bipolar gauze suspension method.

Notes following the operation. Very severe retching and vomiting were constant until the next afternoon, when the stomach was irrigated with sodium bicarbonate solution (dr. j to 0 j) and vomiting ceased for eight hours. On the third day the dressings were found soaked with a dark, foul-smelling exudate of urinous odor and were removed without disturbing the suspending gauze. On subsequent dressings the urinous odor was not detected. The suspending gauze was removed on the tenth day. All renal symptoms disappeared immediately after operation.

About the middle of January, a month after the kidney fixation, the vomiting and the pain in the stomach which had persisted, began to increase in frequency and severity. The vomit was bloody on several occasions. Even a very small quantity of water was ejected. Various procedures were tried for relief and finally complete rest was given to the stomach and rectal alimentation adopted and operation decided upon. Lavage of sodium bicarbonate solution for three days and on the morning of operation prepared the stomach which was found to have a capacity of three pints.

Operation: February 13th, 1901. Chloroform anesthesia. Incision from ensiform to umbilicus in the mid-line. Stomach and pyloric end of the duodenum were brought out of the wound. The pylorus was thickened and a few enlarged glands were felt. The upper anterior part of the stomach wall just above the pylorus was bulged, sacculated and thin. A number of weak gray perigastric adhesions were present in this vicinity merging into the gastro-hepatic omentum. An incision over two inches in length was made, beginning in the stomach, continuing through

the pylorus and extending into the duodenum. The pylorus was found constricted. I inserted a finger into the peritoneal surface of the sacculated portion of the stomach above the pylorus and brought it out of the incision in the pylorus, thus exposing the mucous surface of the sacculus. A large, round ulcer with a thin base and with a diameter just less than an inch was thus discovered, although I had already fixed on the sacculus as the location of the ulcer. The mucous edge of the ulcer was trimmed all around with pointed scissors and the base curetted with a sharp curette until a fresh healthy surface was obtained. A No. 5 chromicized catgut purse-string suture was passed one-eighth of an inch from the trimmed edge around the ulcer. It was passed deep enough to include the submucosa in such a manner that little or no catgut was visible on the mucous surface. The base was sterilized and the purse-string tied. The catgut including the knot was practically concealed beneath the puckered mucous membrane and all evidence of ulcer and catgut thus obliterated. Before tying the suture I had applied a hemostatic forceps to mark the center of the peritoneal surface of the ulcer. With this as a center another purse-string suture of heavy catgut was applied around the peritoneal surface to include a little larger circle than that included in the purse-string around the mucous edge of the ulcer. This was tied. A little of the gastro-hepatic omentum beneath which the ulcer extended was torn through in applying the last suture and this tear was closed by catgut. The first half inch of the duodenal incision was closed by catgut suture applied close to the edges and including all the coats. The remainder of the incision through the pylorus into the stomach was united reversely to the incision to perform pyloroplasty. The first line of suture was of catgut applied close to the edges, to be approximated and through all the coats. Fine silk mattress sutures were now passed after the manner of Halstead to the submucosa approximating the serous surfaces over the thus inverted edges of the pyloroplasty. The abdomen was closed in an hour and a half from the beginning of the operation and during that time nine drachms only of chloroform were used under the careful administration of the resident. Severe acid vomiting occurred after the operation, followed in two days by emesis of large quantities of bile. Solution of sodium bicarbonate finally relieved the bilious vomiting and the stomach became retentive. Solid food was given after two weeks and retained. She did very well until about March 6th, when her rectum began to distress her and to which various enemata and suppositories gave little relief. Finally, March 13th, four weeks after the gastric operation, I examined her rectum and found a large bulging abscess behind the right rectal wall three inches from the anus, which I succeeded in opening without an anesthetic by guiding a straight bistoury along two fingers inserted deep into the rectum. It contained three ounces of flaky pus. The rectal condition was relieved but there supervened a condition of diarrhea which seemed to debilitate her in spite of the fact that she was taking nourishment freely. Slight diarrhea had been noticed, soon after she had resumed solid diet, which disappeared during the development of the rectal abscess. It recurred now quite severely and I soon detected a connection between it and some tenderness and distention in the cecal region. Sunday, April 14th. She was confined to bed with pain in this location. On examination the abdomen to the right of the umbilicus was found decidedly swollen and tympanitic. There was severe pain increased on pressure over the head of the cecum and the right rectus was tense. Her temperature and respiration were nearly normal as for three weeks. The pain continued to increase during the night. The following morning there was a temperature of 103 at eight in the morning, with extreme tenderness over the cecum and appendix. I saw her at noon and immediately operated.

Operation: A three inch incision in the right semilunar line was made so as to control if necessary the right pelvic region. A distended congested cecum with loose unattached edematous adhesions on its presenting surface, was found. The appendix was lightly adherent, its middle third much swollen, covered with large tortuous blood-vessels and containing concretions. Its cecal end was contracted and its distal end looked as if formerly it had ruptured and been covered by adhesions. The villous edematous fringe from the cecum was unusual. The wall of the cecum was thickened, inflammatory in color, except

for an occasional whitish mottling, giving it a tubercular appearance. Near its head opposite the insertion of the appendix, the cecum was distended into a pouch, spherical in shape, the diameter of that portion of the sphere in junction with the cecum proper was smaller than the greater diameter of the pouch. The patient was only lightly under anesthesia and this condition was very apparent in the distended cecum out of the incision during the strain incident to emesis. Old strong adhesions incidental to the development of this condition were found and evidenced a former severe appendicitis and cecitis. The appendix was removed by a thirty seconds application of my electro-thermic forceps and section made within the compressed and agglutinated area. The meso-appendix was hemostased by the same means in twenty seconds. A purse-string suture of catgut was placed above the head of the appendix in the cecum and tied over the thus invaginated stump. A purse string suture was placed around the pouch in the cecum and the pouch turned in restoring the cecum to its normal shape. The abdominal wound was closed after a rapid operation, during which anesthesia was effected by chloroform (dr. 1 2 j) followed by ether (oz. li 3 j). The following morning the patient was free from pain in this region than just before the beginning of the diarrhea a few weeks previously. Since this final operation the diarrhea has ceased and the patient bids fair to be restored to a condition of health she was in before the occurrence of typhoid fever in 1897, when she was robust, florid and quite fat.

NOTE.—June 21, 1901. The patient has gained marvelously in health and is nearly as heavy as in 1897. She has, however, lately developed some pain in left kidney, which may be due to disease, as found at operation, or be due to the fact that her kidney was too firmly fixed.

Remarks.—There can be little question but that the first two conditions operated upon were caused by typhoid fever. During the last two weeks of her attack, while in bed, and for the following month, very frequent and painful urination occurred as is occasionally found due to the infection of the urinary tract by the bacillus of Eberth. The patient cannot now remember if her urine contained pus, and I cannot ascertain. On segregating her urines before the kidney operation I found a few pus-cells in the secretion of the left kidney. Whether this condition could be found earlier during the three years elapsing since the attack of typhoid is questionable. The mobility of the kidney was incident to a great decrease in weight during and after the fever and absorption of the perirenal fat. The subcapsular hemorrhagic effusion with complete dissection of the capsule propria is rare and indicates a condition of the kidney in which great tension existed. It is worthy of note that the effusion under the capsule had the odor of urine.

The large gastric ulcer was undoubtedly post-typhoidal. We know that typhoid ulcers may occur anywhere in the intestinal tract, they have been found in the stomach and even in the lower portion of the esophagus. Occasional vomiting following typhoid and its frequent occurrence later when the stomach became taxed by a more liberal diet shows a causative connection.

The perigastric adhesions found at the second operation and the character of the attack of peritonitis the patient had while in the German Hospital over a year before would indicate a minute perforation at that time. It is possible even that an attack of appendicitis was coincident. The operative features of interest in this case are: first, the method of fixing the kidney by a procedure original with me which I have named the "Bi-polar gauze suspension method," a description of which may be found in *The American Gynecological and Obstetrical*

Journal for December, 1900. Second, the method of dealing with the gastric ulcer, which is new. I can find reference to no case where the mucous surface of the ulcer has been so handled. By this method there is less hemorrhage and interference with the circulation of the stomach wall than when complete resection of the ulcer, including its peritoneal surface, is accomplished. There is some question about the too early digestion and absorption of the catgut used to close the freshened and sterilized base of the ulcer; but if it is placed properly it should hold long enough—besides the outer purse-string suture on the peritoneal surface fortifies it and holds without question.

A third surgical feature was the removal of the appendix during a severe attack by electric forceps. It is one of a number of cases of unperforated appendicitis so treated, all of which had this in common that the appendix was removed without any possible contact with its central infectious canal. The stump is sterile white fibrous tissue with no remaining mucous membrane. In this case the patient who went on the operating table in severe acute pain in six hours was free from pain. This method of removing the appendix by electro thermic pressure has much to do with the lessened post-operative pain.

TYPHOID FEVER OCCURRING IN A TUBERCULOUS PATIENT, AND THE INFLUENCE OF TUBERCULIN ON THIS CONDITION.

By ERWIN FISCHER, M. D.,
of Pittsburg.

A civil engineer, tall and well built, 35 years of age, formerly healthy, but with tubercular tendencies inherited from his father, was taken ill with bronchitis during the summer of 1897, when on a business journey in South Africa. The sputum at that time contained tubercle bacilli in large numbers, but no mixed infection, as was shown by microscopical examination. The attending physician began treatment with Koch's new tuberculin, which was continued by the patient himself, up to doses of 20 mg. of the solid substance, in combination with the internal administration of the various derivatives of creosote. In March, 1898, the expectoration amounted to 60 cc. per day and contained a few elastic fibers, numerous tubercle bacilli, and other microorganisms, but in such a small amount that it did not justify one to speak of a mixed infection. The patient complained of shortness of breath and sharp pains in different parts of the chest. Over the right and upper lobe dulness was present, and upon auscultation rales and crepitation were found, the rales being fine, dry and moist, sharp expiration and inspiration, partly bronchial. In the right middle and left lower lobes there was but slight evidence of rales and crepitation. With the continuance of creosote and new tuberculin (T. R.), the latter from 2 to 15 mg. of the solid substance, until the end of May the subjective symptoms showed improvement, and the condition of the lungs and sputum showed slow, but an unquestionable change for the better, and the amount of expectoration was slightly decreased. At this time he was compelled to leave Pittsburg on business. On his return, July 2d, his temperature was 105°F., pulse 110, respiration 30 and labored. He was suffering from dyspnea. Upon examination absolute dulness, bronchial breathing, and metallic rales were found over the right upper lobe. Rales of various character were found over both lungs, crepitation and sharp expiration in the lower right lung posteriorly. After two days beginning meteorism was noticed, pulse dropped to 100 and was stronger but dicrotic; respiration about 25. The fear that the symptoms in question favored an acute tubercular process yielded to the hope that they nevertheless belonged to enteric fever in con-

sideration of the improvements of pulse and respiration, whereas the temperature remained unchanged. Two days later enlargement of the spleen was noticed upon percussion; Gruber's test positive (Bacteriological Laboratory of Pittsburg, Bureau of Health). Severe abdominal typhus now set in. From July 9th to 29th the patient suffered from intestinal hemorrhage almost daily, which were sometimes quite abundant. His pulse, which was 120, and frequently higher, was feeble and associated with an obstinate high temperature. The number of respirations was in proportion to the pulse rate. Regular injections of camphorated oil became necessary. Several critical collapses were combated with ether, caffeine and nitro-glycerine. The hemorrhages which occurred in spite of scrupulous care in the administration of food, together with the extreme weakness of the heart, greatly handicapped the treatment of the fever by cold water; the cautious application of cool sponge baths excepted. At the end of July the temperature occasionally dropped to 101°F., only to rise soon again. Early in August thrombosis of the left popliteal developed. A definite decrease of temperature was noticed after the middle of August. The stage of steep curves was drawn out over a period of three weeks, always giving rise to the fear of a tubercular lesion. Quinine seemed to exert a favorable influence. The condition of the lungs had already showed some improvement during the period of hemorrhages, and offered a more favorable prognosis. The patient was in bed until September 23d. On October 10th he took his first drive. On October 12th examination showed dulness with a slight tympanic sound over the right upper lobe anteriorly, and posteriorly sharp respiration, rales and crepitation. There were no metallic rales. In the lower left lung posteriorly, slight dulness, rough respiration, a few rales and slight crepitation were found. The pulse was 80, respiration 18 to 20. The patient complained of shortness of breath. Expectoration amounted to 50 to 60 cc., and upon examination was found to be unchanged. October 15th I again took up T. R. injections, starting with 1/500 mg. of the solid substance and gradually increased the dose to 5 mg. by the middle of November. At this time the respiration on the right side was less sharp and on the left side vesicular. There was a decrease in the number of rales, dulness was much less marked, and there was now but 30 cc. of sputum. The subjective symptoms were markedly improved, and the patient was gaining weight. At this time he departed for Pasadena, Cal. and returned in the spring of 1899. At this time the shortness of breath was insignificant. Percussion showed less dulness, and the sputum had dropped to 20 cc. and contained few tubercle bacilli and no elastic fibers. Within four weeks after he commenced work he lost 14 pounds, but this was made up again in the course of time. The dose of tuberculin was gradually increased to 20 mg. in intervals of 4 to 6 weeks. The sputum eight weeks ago amounted to 5 cc. and contained so few tubercle bacilli that great pains had to be taken when searching for them to avoid overlooking them, in spite of centrifugation. The patient had gained considerable weight and complained that his clothes were too small. Gruber's test, which Dr. Matson had the kindness to repeat, was negative. As no sputum was obtainable at this time an examination could not be made. Another course of tuberculin (T. R.) treatment, probably a few consecutive series of it, may be required, and if lack of sputum and physical symptoms should give no evidence of its necessity, test injections will be employed.

The interesting and important question is: did the patient's decided improvement from tuberculosis occur in spite of the typhoid fever, or on account of it? He had given alarming evidence of tuberculosis a year previously, and had been treated with tuberculin and various creosote preparations. His health had improved steadily. On a business journey, in spite of the fact that he was at that time taking creosote, he was taken with typhoid fever of an extraordinarily severe character. In the area of least resistance, that is the most predisposed part, inflammation and destruction took place. What caused the latter, and what arrested it? Con-

cerning the relation of the Eberth bacillus to the respiratory tract, I would, among the publications of later date, especially refer to the one by Fränkel, which does not leave any doubt of its ability to invade the lungs. At the same time pneumococci and other germs are liable to cause such complications. It is possible, also, that it was the tubercle bacillus which destroyed the tissue, weakened beforehand, and more so by the bronchial disturbance always combined with typhus abdominalis. I did not make a bacteriological examination because the sputum could not be obtained, and there were many other things to be thought of. The acute infiltration of the right upper lobe, originally the site of the most pronounced tubercular symptoms, set in when the typhoid infection had brought on the stage of continuous fever. It gave rise to the fear of rapid acute tuberculosis, and after definite confirmation of the diagnosis there seemed to be plenty of reason to be afraid of the tubercle bacilli overflowing the prepared ground, no matter what germs had put it in a suitable condition. What prevented them from doing so? Not likely any property belonging to the patient's constitution, which, in spite of its remarkable vigor and strength of resistance, had previously proved its inherited lack of power against tuberculosis. What extraneous agents could have done the work? Nobody will imagine that creosote was the healing factor. It was not even taken regularly during the critical period. Could it have been the typhoid antitoxins? They had been formed, agglutination took place readily in Gruber's test, which some prefer to call Vidal's, but it does not seem probable that they should have been the superior fighters of the enemy not specific to them, while they were not yet able to put a stop to the one to which they are especially detrimental. Or did the typhoid bacilli, exhibiting surpassing qualities in the struggle for life, destroy those of tuberculosis, or did they create conditions whereby their toxins were pernicious to the latter and in the favor of the patient? Professor Klebs, our great authority on tuberculosis, with whom I had a consultation regarding this case, and also many others, has with much kindness informed me of his experience and studies, showing that the products of certain typhus bacteria have a deleterious influence on the bacillus of tuberculosis, and he has founded favorable results in the treatment of tuberculosis upon those interesting and valuable experiments. But as a disease, typhoid fever has always been considered very dangerous to those suffering from pulmonary tuberculosis, and in the statistics it even maintains a momentous rôle as one of the starting causes of consumption. The most convincing deductions, being based on an equal and strictly observed material, are those from the army reports, as a result of which this statement has been derived. These conclusions, of course, are not antagonistic to the investigations of Professor Klebs concerning the therapeutic use of the former disease's specific bacterial products in conquering the latter, there being a radical difference in the methodical application of precise preparations in carefully calculated doses. It is a widely acknowledged fact that the building up of the body has made the dreaded disease the fountain of unexpected strength to many

frail patients. This influence is not to be considered here, where the perilous condition of the lung and its relative improvement coincided with the acme of fever, hemorrhages and extreme restriction of food. The pulmonary complication ceased contrary to my expectations, as I, and also other physicians, felt positive the termination would be fatal, if the typhoid fever was not. There was something which did not allow the tubercle bacilli, which were undoubtedly liberated in great numbers, to take possession of other parts, although the typhoid infection spread all over the bronchial system in the customary manner. That agent was the immunization which had taken place, thanks to the previous application of tuberculin. Nothing else was in favor of the patient, neither family nor present history nor present condition. The tuberculin had already exerted its power and improved the patient's condition, and I feel fully justified in claiming for it the confinement of the disease to a limited territory and the consequent recovery. I should consider it a neglect of duty to close this communication without heartily recommending the use of Robert Koch's discovery for treatment, not less for diagnosis. It is, as Behring has said, the foundation of the whole modern serum therapy. In disagreement with the master's intention, and own publication, its efficiency was injudiciously exaggerated, and after the disappointments which followed its wrong application, it was condemned in the same manner. Its value is founded upon immunization against the tubercle bacillus and no other. Keeping this in mind, and criticising ourselves first and not the method in case of failure, we will be aware of its limits, avoid harm, and do a great deal of good.

Diagnostic Significance of the Reaction for Sulphocyanates in the Saliva in Diseases of the Ear. E. Urgens (*Wochenmedicinischer Journal*, February, 1901; *Medicinskoje Obosrenie*, April, 1901) found that potassium or sodium sulphocyanate, normally present in saliva, is as a rule absent in suppurative chronic affections of the ear. If the reaction, therefore, is absent or weak, middle-ear disease should be strongly suspected. Likewise, the progress of a case may be determined by the presence and degree of the reaction. The method of testing for the sulphocyanates is as follows: The saliva is collected in test-tubes or on small cotton swabs applied to the ends of the salivary ducts. To this saliva is added a saturated solution of hydriodic acid and starch-paste (in proportion of 1:5). In the presence of sulphocyanates a blue color develops. [A. R.]

Cerebrospinal Meningitis of Influenza Origin Complicated with Acute Anterior Poliomyelitis.—Rendu recently reported a case of cerebrospinal meningitis in a child five years old, before the Medical Society of the Paris Hospitals. (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, 1901, No. 4). Five days after influenza had begun, stiffness was noted in the neck, the head being retracted. Opisthotonos and Kernig's sign were present the next day. Five days later the fever had disappeared, but there was paralysis of both legs, with absent knee jerks and suppressed faradic contractility. Lumbar puncture was performed, and baths at 97°F. given twice daily. The child recovered gradually, the right leg quickly, the left slowly. Two months later the left leg dragged slightly as the child walked. As his brother had an outspoken case of influenza, Rendu assumes that the bacillus was present, entering by the naso-pharynx. It is interesting to note a cerebrospinal meningitis with a co-existing diffuse anterior poliomyelitis. The cerebrospinal fluid was clear, with increased albumin; and no cultures grew. [M. O.]

The Summer Complaints of Children.—With the long continuance of the intense heat of the summer the death records are swollen principally by the heavy mortality among children and feeble persons who are unable to resist the depressing influence of the high temperature and the accompanying humidity. This is especially true in the great cities where the heat is aggravated by the improved pavements, and access to the fields and parks is difficult. There is a factor, also, which is frequently overlooked, but which, we believe, is potent in swelling the ranks of the suffering and dying children in the summer season, namely, the inability to obtain relief at night. Those who have entered the homes of the poor of the city at night have been impressed with the almost stifling heat of the rooms. The lack of ventilation due to the crowding of many individuals into a limited space and the retention of heat by the tin roofing, produce an atmosphere that is most oppressive to the strong, not to mention the little children and those who are weakened by ill nutrition and disease. It is not at all improbable that the depressing environment is the most powerful element in the production of the summer complaint of infants as met with in large cities. Acting upon systems thus depressed and deteriorated, the unclean bottle and rubber nipple find most suitable soil for their deplorable work. The acute diarrheas of infancy quickly follow, and notwithstanding the truly noble and well-directed efforts of the district and dispensary physicians to combat the ravages of disease, their labors are too often ineffectual. Their task is truly that of Sisyphus. As long as the unfavorable surroundings continue it is an almost impossible task to relieve the drooping infants. There are, however, some measures that may be adopted whereby the chances of recovery will be materially increased. Primarily among these should be mentioned the observance of absolute cleanliness of the nursing-bottle and its appurtenances. The use of a bottle which can be cleansed in every portion by the direct application of the finger and the plentiful use of a solution of sodium bicarbonate will do much to hinder the fermentative processes which,

once inaugurated, result disastrously. When not in use both bottle and nipple should be well cleansed and kept immersed in the bicarbonate solution until the subsequent feeding. Careful selection of the milk or artificial preparations, together with pasteurization of each feeding, is next important in the prophylaxis of the intestinal disorders of infancy. Whenever feasible the child should be kept for as many hours as possible in the open air and preferably in the parks and squares of the vicinity or on the trolley cars or local steamboats. The clothing should be light and clean and every effort should be made to keep the child cool while avoiding chilling from draughts. If, notwithstanding these efforts, the bowels become inflamed, frequent intestinal douching with normal saline solution will be found both grateful and healing, and a valuable adjuvant to the medical treatment which may be prescribed. It is not our intention to lay down any hard and fast rules for the management of these cases. The text-books and current literature teem with valuable suggestions. Whatever course may appeal to the physician as most suitable in the given case, an observance of the foregoing suggestions will be found to materially aid the efforts taken, and will, we believe, lessen the frequency of a fatal termination. The diseases arise from a combination of heat and uncleanness, producing lessened body-vitality, and while it is necessary to institute a course of systematic treatment the main attention should be given to correcting the causative conditions.

Zomotherapy in Tuberculosis.—The precipitous quest for specifics in the treatment of disease sometimes prevents us from giving due attention to more simple but not less important therapeutic procedures. In no disease is this more true than in tuberculosis, for, with the exception of the constructive remedies, the therapy of this affection is practically still in a chaotic condition. A form of therapy, although still in an experimental condition, but nevertheless deserving of recognition, is that known as "zomotherapy," which may be broadly defined as the administration of raw meat or its active ingredients. The word itself is derived from a Greek

word signifying broth, and will be recalled by students of Greek as appearing in the description of the "black broth" of the Spartans. The word was first proposed by Richet and Hericourt. (*Semaine med.*, 1890, p. 404.) These observers stated, as a result of their experiments upon dogs, that when these animals were fed with raw meat the development of experimental tuberculosis was somewhat retarded, while on the other hand, animals kept for purposes of control and who were fed upon ordinary diet, quickly succumbed to the experimental inoculation of tubercle bacilli. Henry Harper (*Lancet*, March 9, 1901, p. 694) claims to have obtained good results from the administration of pure urea in human tuberculosis, and his experiments even show that the addition of urica to culture media inhibits the growth of tubercle bacilli. The most recent observations on this subject, however, appear to be of quite a dissenting character as evidenced by the researches of C. Fränkel and G. Sobernheim, of Halle, Germany (*Berliner klin. W'och.*, July 15, 1901, No. 28), who claimed to have found so little difference in the ultimate condition of animals that had, and those that had not, been fed with raw meat, that they discarded the matter as unworthy of further experimentation. This controversy should all the more awaken the interest and stimulate the zeal of investigators, inasmuch as several imperfectly recognized factors seem to show that this form of therapy has for its basis several well authenticated facts. It will occur to every observer that the negro, whose proneness to tuberculosis is so well known that it need not be discussed, partakes of but little food that is rich in urea; and the southern portion of the United States, where he lives practically in the open, still is ravaged to an appalling degree by tuberculosis. Another point of considerable importance, but one still unsupported by definite statistics, is the question whether individuals with a uric acid diathesis are not less affected by tuberculosis than others. If zomotherapy proves clinically successful, it still remains for biologists and chemists to show whether the action of raw meat is simply to be attributed to its stomacheic properties, in that it increases the assimilation of nourishment, as claimed by Chantemesse (*Sem. med.*, 1900, p. 203), or whether, as Richet believes, substances are present in meat juice which retard the development of tubercular granulations, or, finally, whether, as Maragliano believes, the meat juice acts as an irritant, thus giving rise to the formation of antitoxic materials in the organism.

Medical Representation in Hospital Management.—The agitation that has been aroused by the action of the over-zealous secretary of the lay board of managers of the National Hospital for the

Paralyzed and Epileptic in London in virtually proclaiming independence of, if not contempt for, the medical profession, has called acute attention to the paradoxical tendency manifest in certain quarters to eliminate medical men from the control and management of hospitals. The specious plea has been made that the presence of medical men on such boards of management is likely to give the former a preponderating influence, which it is feared will not be exercised impartially or judiciously, or to the best interests of the patients, but that it may result in unjustifiable therapeutic experimentation, or what not. Further, the charge is usually made that medical men are deficient in business qualifications, that hospital management is a business and should be conducted on business principles.

At the outset it is to be feared that those who hold such narrow views are beyond the influence of argument.

In the first place, medical men generally are, by very reason of their training and their profession, most tolerant, most broad-minded, and most judicial in their judgments, and they will yield to none a sense of greater humane consideration for the well-being of those entrusted to their care. While it is true that the physician is, largely in consequence of more important demands on his time and energy, disinclined for the details of business matters, he is often possessed of a fine and ethical business judgment; and, of course, none can take his place in dealing with matters appertaining to the professional aspects of hospital government. For these reasons any steps looking to the exclusion of the medical man from the boards of government of hospitals, or calculated to restrict his influence in this connection, must eventually result in serious injury to such institutions. That this is so would seem to be the consensus of opinion held by those—both lay and medical—best fitted to form a judgment on the subject, as exhibited in a symposium on hospital management prepared by the enterprising and versatile editor of the *Practitioner*, and presented in the June number of that journal.

To the question as to whether hospitals should be wholly under lay control, or whether the medical staff should have a voice in the management of their affairs, there is practically unanimity of answer that the medical staff should have some kind of representation on the governing body in order that such management shall be in the fullest measure successful. This opinion is expressed not less emphatically by laymen than by medical men. The symposium is a most valuable one and should receive the careful perusal of all who are interested in hospital work.

Pathological Dreaming.—Students of psychiatry have long recognized the similarity which dreams bear to the delusions of the insane. The subject is a deep one—not easy to grasp or to illumine. It is somewhat subliminal, and only too likely to excite the scoffs of the uninformed. And yet, although this subject pertains to dreams, it is a very real one. Dreams may not only have a pathological significance—they may be pathogenic. Here is the important point. Dreams may constitute a fruitful night-soil out of which may grow a crop of poisonous weeds. This is true of the neurasthenic, the hysteric and the insane. The French (Gilles de la Tourette, Janet and others) have shown that in hysteria there is a form of reverie or delirium (which is practically the same as dreaming) in which the patient seems to herself to lead such a vivid and real existence that thenceforth the contents of the dream are an actuality to her. From this morbid state arise questions of medico-legal importance. The false witness sometimes borne by hysterical patients comes from this sort of mental perversion. Character has been jeopardized by it. This has been called "pathological lying," or, as it was named by Delbrück, *pseudologia phantastica*. This term is not intended as a mere euphemism for calling a person a liar. It describes, on the contrary, a genuine psychiatric fact.

We are reminded of this subject by an interesting paper by Professor Pick, of Prague, a translation of which appears in the July number of the *Journal of Mental Science*. Pick deals with a rather different phase of the subject—one which is more nearly related to day-dreaming. It is odd that no one has yet, so far as we know, completely explored the psychiatric architecture of castles in the air. Professor Pick has taken a class of patients who are evidently neurasthenic rather than hysterical, and whose psychiatric life is curiously dominated by a succession of dream-pictures. The patients, while fully conscious of the unreality of these reveries (in which respect they differ from patients with delusions), yet react in various ways to them, even to the extent of talking aloud and gesticulating, and are in various ways incapacitated by them. Hence these day-dreams, or reveries, are distinctly pathological; in fact, their pathological character was recognized by the patients themselves, who sought medical advice. These dreams have sometimes, although by no means always, an erotic tinge, even associated with onanism. This is the "auto-crotism" of Havelock Ellis. Professor Pick describes his cases in detail, giving interesting autobiographical notes. It is a characteristic Teutonic paper—minute, exact and instructive.

More Plague in San Francisco.—There is good reason to feel satisfied that the slight recrudescence of plague in San Francisco finds the local and national health authorities in harmony as regards both the diagnosis and the treatment. This is as it should be and will inspire the rest of the country with confidence. The situation has its special difficulties because of the characteristics of the oriental population to which the disease has thus far been limited, but the latest reports indicate that this situation is held well in hand. Dr. Kellogg and Dr. Ryfkogel, experts of the city health office, have had experience, and they also have candor and fearlessness in meeting the exigencies. Assistant Surgeon Rupert Blue, of the Marine Hospital Service, sent his official report to the Surgeon General under date of July 20th.

From this report we learn that up to that date five new cases had occurred. One of these was in a Chinaman who had only just come to the city on July 1st, and who died four days later. This case appears to have had no relation to the four other cases, which occurred in one house among some Japanese prostitutes. These women had lived in this house for some months at least, and the origin of the infection seems to be a mystery. Two foci of infection thus appear to have existed. Of the four cases that occurred in this brothel, three were fatal, but one girl at last reports was recovering. This is the only case of recovery from plague that has yet occurred in San Francisco. Dr. Blue says that the Japanese are not so secretive as the Chinese, and have more confidence in scientific medicine. Hence these cases were studied without much difficulty. Blood specimens were obtained before death, and a diagnosis made. The pathological and bacteriological findings were all confirmatory of the diagnosis. Now that we are once more positively assured that plague has secured a foothold in the United States, we need to be all the more alert. Of a few things also we may be assured. First, secrecy will not secrete the plague; and, second, the prevalence of this disease at any particular spot whatsoever in this country is a matter not of mere local interest, but of general importance. The whole country is interested and has a right to be interested. Experience in other countries, notably England and Australia, has proved that an energetic administration can do much to control this formidable disease.

Milk-borne Scarlet Fever.—Dr. D. S. Davies reports (*Journal of Hygiene*, July, 1901) the statistics of an epidemic of scarlet fever in Clifton, a sub district of Bristol, England, containing about 47,000 people. A certain dairy, designated X, was suspected, because at the time of the outbreak a boy who had

access to the milk vessels there was sick with what seemed to be an ambulant case of scarlet fever, and a week later two of his brothers were seized with typical forms of the disease. Two dealers in Clifton served milk from this dairy, and some milk was sent directly from it to the city. The milk from X was distributed to 200 houses, in 42 of which cases (66 in all) of the disease occurred. During the same period, 85 other dealers not receiving any milk from X, served 6922 houses, among which 9 cases occurred. One of two dealers mentioned above also obtained milk from another dairy, but two dealers who obtained milk from this dairy and none from X had absolutely no cases on their routes. The distribution of the infection is vividly exhibited by a colored chart of ingenious form.

The Obstetrical Stigmata of Degeneracy.—While both the physical and the moral stigmata of degeneracy have for some time been well recognized, R. and H. Larger were the first to state, in their thesis on the subject (quoted in the *Bulletin Medical*, July 6, 1901, No. 53) that they consider all variations from the physiological type in conception, in pregnancy, and in labor, to be obstetrical stigmata. Among the anomalies of conception they place sterility, twin-pregnancy, and ectopic gestation; among those of pregnancy, hemorrhage, placenta previa, adherent placenta, premature rupture of the membranes, hydatidiform mole, velamentous insertion, etc.; among those of labor, abortion, premature delivery, prolonged labor, and all presentations other than the usual L. O. A. When any of these conditions occur, one or both of the parents are degenerates, either hereditary or acquired. Besides, the authors consider puerperal infections, such as eclampsia or phlegmasia alba dolens, also signs of degeneracy. They have collected material from private practice, from the clinics of Baudelocque and Tarnier, and from a number of physicians. Statistics of over 600 women and 2000 obstetrical anomalies have been tabulated. In every case antecedents showing degeneracy were secured. Anomalies may be due to plainly marked degeneracy in the husband, the wife, or both; and it seems probable for anomalies of presentation to be hereditary through the male as well as through the female. In some cases the only sign of degeneracy may be the series of abnormal presentations; especially when the husband and wife are closely related. The acquired causes of degeneracy, such as epilepsy, alcoholism, syphilis, tuberculosis, etc., have the same result upon the offspring. The subject matter of the thesis is excellently expressed, and forms absorbing reading. As a final result, sterility occurs in the individual, forecasting the extinction of the race.

We quote from this paper merely as a matter of

interest, for we do not mean to endorse its conclusions. These seem to us in many respects to be extravagant and far-fetched.

The Nerve to Run a Locomotive.—A prominent railroad official has recently portrayed, in rather vivid colors, the disastrous effects on the human system caused by running a fast locomotive. He is quoted as saying that this occupation breaks down a man's nerve. The engineer is depicted as descending from his cab, after a long and fast run, "with the heavy step of exhaustion; the elasticity and agility of the start all gone." It is upon the nervous system that the work of running a "flyer" bears heavily. The engineer becomes timorous; he can no longer hold his engine to its work; he falls behind his schedule time, and always brings his train in late. This loss of nerve, it is said, is suffered by the stoutest heart, but the length of service varies. Some men will last for twenty or thirty years, while others give out much sooner. All this applies to running fast trains. On the two Atlantic City lines, to which reference was especially made, a speed of more than a mile a minute has come to be the usual thing.

Although somewhat overcolored, this description is not altogether inaccurate. We imagine, however, that many an old engineer would laugh at being told that after every run "he had the heavy step of exhaustion." He might confess to being a trifle stiff after two or three hours in the cab, but he would probably deny that his nerves were in any way shattered. Any casual observer in Broad Street Station can see for himself that the engineers have not the appearance of being neurasthenics. As long as everything goes well we doubt whether it is any greater trial to the nerves to run a fast train than it is to run a slow one. It is only when accidents occur that an engineer is likely to become profoundly neurasthenic, and to be ever after unfitted for his work. This may be so, even though the man is physically uninjured. Old railroad men can tell of plenty of such instances. We knew recently of an engineer who had run fast trains on the Pennsylvania Railroad for thirty years without an accident, but who finally ran into a little "smash-up" in which he himself was not at all badly injured; and yet he could not return to his cab for more than a year. He had a fine case of traumatic neurasthenia. We refer to this subject as an illustration of the diseases of occupation.

An Increased Number of Eosinophiles in the Blood a Sign of Appendicitis.—Laignel-Lavastine reported four mild cases of appendicitis in which he found that the eosinophilic cells in the blood increased to 3, 4, 5, and even 9% from the fourth to the eighth day of the acute attack, to return again later to 1%. He considers this a pathognomonic sign of catarrhal appendicitis. This increase of the eosinophiles is also seen in Duhring's disease and urticaria. It is an aid in the differential diagnosis of mild appendicitis. (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, April 25, 1901, No. 13). [M. O.]

Reviews.

Oral Sepsis as a Cause of Septic Gastritis, Toxic Neuritis and other Septic Conditions, With Illustrative Cases. By William Hunter, M. D., F. R. C. P., Senior Assistant Physician, the London Fever Hospital; Physician to the Electrical Department, Joint Lecturer on Practical Medicine and Pathological Curator, late Pathologist, Charing Cross Hospital. London, Paris, New York and Melbourne. Cassell & Company, Limited 1901.

From an esthetic viewpoint a mouth full of decayed teeth and old stumps is repulsive, and many mechanical appliances have been devised by the prosthetic dentists to supply a deficient dentition. Plates, bridges, crowns and fillings are of extensive use among the upper and middle classes.

The book before us for review shows, first, the evil effects of necrosed and carious teeth and roots on the mouth and on the general health; and second, the manner in which the appliances of the dentists, by collecting food particles, assist in producing local and general septic conditions in the gastrointestinal tract, and thence in the entire system.

It is a well known fact that wounds in the mouth heal rapidly and yet, the sepsis connected with diseased teeth is of a peculiarly virulent character, much more so than the pus derived from the soft tissues. In 95.3% of cases of dental caries the offending organism is the bacillus gangrenæ pulpæ, which is capable of producing its effects in an alkaline medium. The author believes that for every case of gastric affection traceable to pyorrhea alveolaris, a hundred cases no less marked are daily met with associated with other septic inflammatory conditions of the gums so commonly met with around necrosed carious teeth and roots. He believes that dental disease is a cause of indigestion in consequence of being a continual source of septic poisoning and septic gastric infection. This process may go on until it finally results in chronic gastritis with atrophy of the glands. Other results of oral sepsis are fever from septic absorption, septic rashes, purpuric hemorrhages and bleeding from the gums, profound septicæmia and toxic neuritis.

The book should be read by every physician and being read should serve to induce deep thought and to create a lasting impression. As the author says: "No physician would tolerate for a moment that a person who has a foul septic ulcer on his arm should periodically suck it; and yet this is what is allowed to go on in the case of the mouth for periods of years unheeded alike by doctor and patient." [J. M. S.]

Sixteenth Annual Report of the Bureau of Animal Industry, 1899.—Department of Agriculture, U. S.

The 764 pages which compose the Sixteenth Annual Report of this bureau contain, as is usual with these reports, much that is of interest to physicians generally and especially those interested and working in pathology and hygiene. Of especial interest are the notes on parasites by Stiles, in which appears an excellent account of *Paragonimus Westernmanni*, a lung fluke, which is well illustrated with fine plates. A careful digest of the literature concerning this parasite, and the disease which it causes in man and animals, adds greatly to the value of the article. Since this parasite may cause a Jacksonian form of epilepsy if it develops in the brain or meninges, and a chronic hemoptysis which has several superficial resemblances to phthisis, it behooves the general practitioner or to be well acquainted with the disease and the parasite. The lung fluke is common in the East and has recently been found in this country. A good account of *Pseudo Tuberculosis* or *Caseous Adenitis* is given. This disease commonly attacks sheep and is caused by Preisz's bacillus. Excellent plates of the macroscopic and histological appearance of the lesion accompany the article.

A curious disease of horses, *maladie du coit*, which is venereal in character, is discussed in a lengthy paper in

which an account of a recent outbreak in Nebraska is detailed.

Anyone may considerably enhance his stock of general knowledge by merely turning the pages of this report, but the man who is interested in scientific and hygienic food production, parasitology and comparative pathology, cannot help but pause, read and study, and thereby profit, when he opens this volume. [R. L. P.]

Report of the Commissioner of Education for the Year 1898-99. 2 Vols. 8vo., pp. XCII, 2518. Washington. Government Printing Office. 1900.

These two portly volumes contain a vast amount of information on a wide range of topics in the domain of education, general and special, gathered from a variety of sources, immediate and remote. The many phases of the subject are presented in 51 chapters, some of which are elaborate in detail and include a large array of statistical data. [A. A. E.]

On the Question of the Fate of Bacteria in the Organism of Immunized and Non-Immunized Animals.—S. I. Goldberg, in a dissertation delivered before the Military Academy (summarized in the *Bolnitchnaia Gazeta Botkina*, Vol. XII, No. 3) gives the results of his experiments, which were performed as follows: Pure cultures of pathogenic organisms were injected into the blood of animals, and cultures made from time to time to determine the length of time during which the organisms remain in the blood current and the degree of their virulence. The animals were finally killed and their organs examined. Several other problems in connection with immunity received attention. The following results were obtained: Rabbits immunized against bacillus pyocyaneus became more resistant to infection with anthrax or typhoid bacilli. The organisms injected into the blood current disappeared in 4-8 hours, except anthrax bacilli, which were present in some up to the time of death. In the animals immunized against bacillus pyocyaneus the disappearance of the anthrax bacilli was also inconstant. During the first few hours following the injection the bacilli accumulated principally in the liver, this having been more marked in the immunized animals. This retention of the bacteria by the liver is not passive but depends on active phagocytosis on the part of the endothelial cells and the leukocytes. As infection proceeded, the accumulation of the bacteria took place principally in the spleen where they remained the longest. The organisms retained their virulence within the organs of immunized animals and were capable, under favorable circumstances, of producing local infection (pericarditis, pleuritis and cholecystitis). In the animals immunized against bac. pyocyaneus the bacteria accumulated in the spleen, while in those immunized against typhoid they were mostly found in the bone-marrow. The conclusion is drawn that in the former the spleen and in the latter the bone marrow are the most important defenders of the organism. The agglutinating properties of the blood were not always in proportion to the degree of immunity, and therefore there is no relation between the agglutinating and bactericidal properties of the blood. The immunity depends principally on the activity of cellular elements of certain parenchymatous organs. Phagocytosis is not the only factor in immunity; the bactericidal properties of the tissues, the antitoxins and other factors play an important role. [A. R.]

A Case of Acute Leukemia.—A. Swocchotoff (*Bolnitchnaia Gazeta Botkina*, May, 1901) reports the case of a man, 23 years old, who developed rather suddenly hematuria, bloody stools and pain and bleeding from the gums. Personal history good, except an obscure attack of rheumatism, from which he suffered for about 3 weeks and recovered completely. On examination the mucous membranes appeared pale and cyanosed, the lymphatic glands somewhat enlarged and the skin covered in various places with small hemorrhagic spots. Both liver and spleen were greatly enlarged. An examination of the blood showed 3,622,000 red and 8,000 white corpuscles. The patient became rapidly worse, suffering from severe hemorrhages and excruciating pains in the bones, and died on the fifth day of admission. [A. R.]

Correspondence.

MISSTATEMENTS OF THE ANTIVIVISECTIONISTS
AGAIN.

By W. W. KEEN, M. D., of Philadelphia.

To the Editor of the Philadelphia Medical Journal.

San Francisco, July 8, 1901.

On January 21, 1901, I sent a reply to James M. Brown, president of the American Humane Association, in response to a letter from him challenging me to produce proof of inaccuracy in the references to a number of certain alleged experiments and of garbling the reports of the same. My reply was published in *The Journal of the American Medical Association* and the *Philadelphia Medical Journal* of Feb. 23, 1901.

In reply I received a letter from Mr. Brown saying that he expected to spend the month of February in California, and could not give attention to my letter until his return.

Mr. Brown seems to have been detained in California much longer than expected, for up to the present moment—nearly six months—I have received no further reply whatever. Indirectly, however, a certain reply has been published in the form of an anonymous pamphlet entitled "The Reality of Human Vivisection," which is called a "review" of my letter.

Not long since I had the pleasure of attending a lecture to one of his classes in moral science by Rev. Dr. Faunce, the accomplished president of Brown University. Among the virtues which he discussed was "Courage" and he pointed out the moral cowardice of anonymous letters. While such a letter is an instance of private moral cowardice, an anonymous pamphlet such as this is an instance of public moral cowardice. An honorable open foe I at least respect; one who skulks behind anonymous pamphlets I despise. The antivivisectionists seem to delight in such secrecy and anonymous attack.

There are four publications on this subject up to the present moment, to which I shall hereafter refer by number, except the last which I shall call the "review." 1. In senate document No. 78, 55th Congress, 3d Session, the last of a collection of certain antivivisectionist papers is one entitled "Human Vivisection," signed "A. Tracy." I should like to know who this mysterious "A. Tracy" is.

2. There is a pamphlet entitled "Human Vivisection," third edition, printed for the American Humane Association in 1900, which reprints this paper (with omission of "A. Tracy's" name) and adds to it a long continuation of the misstatements of the first. This is anonymous.

3. There is a small pamphlet entitled "Human Vivisection," published by the Humane Society, Washington, D. C., chiefly a relash of the misstatements of pamphlet No. 2. This is also without the name of any author.

4. Now comes the last pamphlet, the "review" of my letter. This is not only without the name of the author, but without even that of a publisher. It is simply dated "Boston, 1901."

The character of every one of these publications, however, is such that I do not wonder that the author wishes to conceal his identity.

The "review" (No. 4) re-prints Mr. Brown's letter to me and at the end adds: "No sufficient rejoinder to his [my] letter [in reply to Mr. Brown] would be admitted to the columns of these medical periodicals." (*The Journal of the American Medical Association* and the *Philadelphia Medical Journal*). The duplicity of this sentence is evident. The ordinary reader for whom it is evidently intended, would understand that a reply had been sent to the editors of these medical journals and that they had declined to print it. This is absolutely untrue. No such communication has ever been received by the editor of either of these journals. The critical reader will see that the sentence just quoted does not state that such a communication has been rejected. But for one critical reader a thousand casual readers will get the impression which the sentence was evidently intended to convey.

It is impossible for me to take up all the misstatements and misrepresentations contained in the 32 pages of this last anonymous "review," nor is it necessary to do so. That I should be honored from such a source by vivisection and misrepresentation, I expected, of course, but I did hope at least that there would be an honesty of statement to which no exception could be taken.

The author, however, is a very curious person who does not seem to be limited by the ordinary laws of either fair dealing or truthful statement.

Moreover, he would be a very poor lawyer. Most of the evidence cited by him is derived from published reports by certain medical men. Having, therefore, chosen his witnesses, and put them on the stand, he would not be allowed in any court of law to discredit his own witnesses by selecting part of their testimony as trustworthy and rejecting part as unworthy of credence. And yet, throughout this "review," while the anonymous author is eager to accept the statements of the various authorities as to what they did, he declines to admit their statements as to their results, or else misstates them, going so far as to assert that the statements of the physicians cited concerning the recovery of their patients are "utterly valueless."

In reply to Mr. Brown, I used the following language: "Let me again state clearly the question at issue. *It is not whether the experiments meet with my approval, but solely whether the reports of them in the pamphlet issued by the American Humane Association are reliable and accurate both as to their sources and substance.*" At the Hearing before the Senate committee, I distinctly twice over expressed my utter disapproval of many of the experiments referred to in the original pamphlet (No. 2). The condemnation is quoted both on page 1 and page 3 of the anonymous "review;" yet, in spite of these two statements and the third in my letter to Mr. Brown, just quoted, the author represents me throughout his "review" as the apologist and the advocate of such experiments, thus publishing, yet at the same time wilfully ignoring my repeated statements to the contrary.

In my letter to Mr. Brown, in support of my accusation that many of the references in the pamphlet on "Human Vivisection" are "vague and indefinite," I cited fourteen instances of quotations from newspapers, five of which were without date, and I added six other instances of "vague and indefinite" references not to newspapers. I commented upon the unreliability of newspapers as a source of authority in medical matters.

Let us see how the anonymous reviewer attempts to meet this issue. The facts he does not and can not deny. In the first place he claims that I have changed the issue from "the question of vague and indefinite quotation" to that of vague and indefinite references. When I stated at the Senate Hearing (stenographer's report): "Many of them are so vague and indefinite that I could not look them up," it must have been clear to anyone of common sense that I referred to the references to the experiments, and there was no misunderstanding on this point in the letter of Mr. Brown, who asks: "To what other of the references above given did you refer when you informed the Senate Committee that 'many of them were so vague and indefinite that I could not look them up?'" I was challenged by Mr. Brown to adduce examples of "vague and indefinite references," and this challenge I successfully met.

On page 22, the anonymous reviewer says: "Of the fourteen journals referred to, *every one* conveying a statement of fact—save one—had its name and date of publication plainly given." Here it will be observed that a distinction is drawn between references to articles "conveying a statement of fact," and those which do not relate to statements of fact. My indictment against the pamphlet on "Human Vivisection" (No. 2) was and is that many of the references are so "vague and indefinite" that the original sources of alleged quotations can not be consulted, and that some of the reports are "garbled and inaccurate." It may be just as important to determine the accuracy of a reference to an expression of an opinion as to learn the facts upon which the opinion is supposed to be based, and to charge me with an evasion of the issue because I did not restrict myself solely to one particular class of references, but pointed out the vague and indefinite character of all classes of references in the pamphlet, is too absurd to require further comment.

As a matter of fact, as pointed out in my letter to Mr. Brown, there are no less than five citations or reports of experiments in pamphlet No. 2 for which either no reference whatever is given, or the one inserted is wrong or so vague and indefinite that the original can not be consulted.

On page 9, the anonymous reviewer says: "It was pointed out by the president of the American Humane Associa-

tion that, with one exception, every phase of experimentation specifically mentioned had some reference to a medical authority." It is incredible that the reviewer should not have known the falsity of the statement attributed by him to the president of the American Humane Association, or he may think that in this strangely worded sentence he has constructed some loophole of escape through such avenues as may be afforded by throwing the responsibility for a false statement upon another, or by such equivocal phrases as "every phase of experimentation," "specifically mentioned," "some reference." There are in fact in the pamphlet of the American Humane Association seven instances in which reference to a medical authority for the experiments mentioned is lacking, and in addition the sole authorities for an important part of the statements regarding Sanarelli's experiments are the correspondent of a daily newspaper and a speaker at a convention of the American Humane Association.

Let us see how the reviewer tries to meet my demonstration of numerous instances of "garbled and inaccurate" quotations in pamphlet No. 2. Here again the facts can not be denied, but an attempt is made to minimize their importance.

1. "Brevity of quotation is often absolutely necessary" ("review" p. 9). Why, then, as I pointed out in my letter were whole sentences added, which do not appear at all in the original?

2. Errors are described in the "review" as a "translator's exaggeration" (p. 6) "blunders of a copyist" (p. 6) "errors of a translator" (p. 7). So, then, it is now conceded that the pamphlet does contain "exaggerations," "blunders," and "errors." It contains not merely "errors of a translator," but deliberate falsifications and misrepresentations. When a translator says what the author did not say; when the word "collapse" is translated "final collapse" and an oration is made upon the death of patients who did not die; when the American Humane Association in reference to these very cases quotes on the cover of its pamphlet "Is scientific murder a pardonable crime?" in spite of the published fact that the patients referred to did not die; when the translator again and again interpolates words, phrases and sentences which do not exist in the original, when essential phrases and paragraphs are omitted, these I submit are not the mere "errors of a translator" but deliberate misrepresentations. Instances of all of these I furnished Mr. Brown in reply to his challenge.

The pamphlet, moreover, contains, as I have pointed out, false or misleading quotations which could not be attributed to "errors of a translator" as they were from English sources. One can only hope that hereafter the "translators" and "copyists" employed by the antivivisectionists may be more accurate, or rather that the men and women back of these poor employees may be willing not to distort and suppress the truth in order to effect their purpose. It is a safe rule, I find, not to believe any statement of an antivivisectionist until its accuracy is established by reference to the original source from which the alleged statement or quotation is derived.

3. My charge of garbling and inaccuracy of quotation is practically admitted, but the reviewer states (p. 15): "For one of them [the translations] was the American Humane Association responsible in any way whatever." It is now rather late in the day to advance this disclaimer, after the section on the inside of the cover of the pamphlet of the sentence: "The facts are indisputable," and in the preface over the signature of the president and secretary of the association: "In each case, the authority is given." It is a favorite trick of antivivisectionists to attempt to throw in this way responsibility, when confronted with incontrovertible evidence of false statements, as is illustrated in the controversy between Miss Cobbe and Mr. Horsley.

I shall be curious to see the fourth edition of this pamphlet. For it I now furnish one more instance of false statement, the evidence of which was not in my possession at January. Even Mr. Brown admits that to this "the reference may, perhaps, be called indefinite." I submit that "perhaps" it may, for no book, journal or any other publication was named. The instance I refer to is Jansen's lecture purporting to be quoted on page 26 of pamphlet No. 2. The lecture was published in a well-known journal, *Centralblatt f. Bakteriologie u. Parasitenkunde*, 1891, Vol. 2, p. 40. So gross is the falsification that the reference is "perhaps" wisely omitted. The first phrase of the quotation is as follows: "When I began my experiments with smallpox pus, etc." This is an absolute untruth.

What Jansen used was not smallpox pus at all, but sterilized, diluted vaccine lymph, and sterilized blood serum from vaccinated calves, which could do no more harm than injecting so much water. The entire extract is inaccurate as a translation. There can be no question but that the substitution in this alleged quotation of "smallpox pus" for "sterilized vaccine lymph" can not be attributed to the mere "error of a translator," but is a deliberate falsification, and this in a pamphlet introduced with the statement to the reader: "The facts are indisputable!"

Much has been made of my statement that I could only find in the pamphlet references to "two experiments" in America. My reason for this statement was very simple and perfectly evident to any honest-minded reader.

In the pamphlet "Human Vivisection" (No. 2) there are a number of experiments related, the numbered ones beginning with the following on page 1: "1. Vivisection Experiments upon the Insane." Under this title several experiments, all of the same nature and by the same individual, are reported, eight being referred to in all. On page 5, appears, "2. Vivisection of Children in Boston," and under this a number of experiments, all by the same person, are referred to. Anybody with common sense would see that when I referred to "two" instances, I did not mean two individual experiments, but using the classification of the pamphlet, I referred to Nos. "1" and "2" on pages 1 and 5. In fact I specifically referred to these pages and mentioned various experiments under each caption.

I presume, however, that it is useless to expect fairness from an ambushed enemy.

The anonymous "reviewer's" suggestion that as I was President of the American Medical Association last year therefore I am responsible for every paper read before that body—when there were hundreds of papers read in over a dozen Sections before several thousand members—is so amusing that I pass it by with a smile at the author's simplicity.

One sentence of my letter I wrote perhaps better than I knew. In the account of Sanarelli's experiments a certain sentence, "I have seen unrolled before my eyes, etc." was quoted by "A. Tracy" in the original paper (No. 1). In that pamphlet two references were given, one to the *British Medical Journal*, the other to the *New England Medical Monthly*. I stated that this entire sentence occurred in neither of these journals and I added: "Whether it is quoted from some other source not indicated or has been deliberately added, I leave you or A. Tracy to explain." The "reviewer" explains that this quotation was from another source not indicated (surely this was "vague and indefinite"), namely, Sanarelli's original Italian paper, though no reference was made to it.

Inasmuch as in my letter to Mr. Brown I gave the reference to Sanarelli's original paper the anonymous author of the "review" pays me the compliment of supposing that I am a facile Italian scholar, and therefore, that I was perfectly aware that Sanarelli himself wrote this sentence. "With this volume in his hands, the original article open before his eyes," says the "reviewer," "would he have us believe that he did not take the trouble to compare and verify the only quotation from it which appears in the pamphlet? He did not see it? Credat Judæus Apella! There are limitations to credulity. But how queer must be that sense of honor which would permit a man to make a disgraceful imputation knowing all the while that every word of it was false!"

The simple facts of the case are these. Unfortunately I am not an Italian scholar, and have never even seen Sanarelli's original article. In order to find out the real facts, I wrote to a friend who reads Italian well, to learn whether these five patients really died, as the American Humane Association pamphlet (No. 2) asserted. He replied giving me the original reference, and stated that not one of them died.

As the "reviewer" points out that this quotation by "A. Tracy" was from Sanarelli's original paper, a very interesting enquiry arises, viz., if "A. Tracy" in Senate document No. 78, as is now claimed, quoted from this original paper of Sanarelli, it is in order for him now to explain how it is when Sanarelli's original paper states that all of these patients recovered he states that some, if not all of them died, and how he dares to quote nearly a page of oratory about "scientific murder" and "assassination," based upon this false statement.

On page 26 of the anonymous "review" the author disputes the value of tuberculin as a test for incipient consumption in children. Were it worth my while I could give

him references to disprove this statement, but in view of his amazing ignorance of modern medical progress as evinced by the next statement, I do not propose to take the trouble. He says "Dr. Keen knows perfectly well, in the first place, that phthisis, however early discovered, is not in all probability a curable ailment." Has he never made a postmortem examination and found a cured phthisis? Has he never visited, or even read of, the Adirondacks, or Denver, or Colorado Springs, or Minnesota, or Arizona, or New Mexico, or a score of other places? Has he never read of the many books and pamphlets on sanatoria for consumptives? Does he know nothing of these modern movements? Koch's discovery of the bacillus of tuberculosis by experiment upon animals in 1882 has done more to help in curing consumption and other forms of tuberculosis than any other one means and especially by its early recognition. If he will consult the recent Prize Essay on "Tuberculosis as a Disease of the Masses and how to Combat it," by Dr. S. A. Knopf, of New York, he will be made aware of the facts. This essay was awarded the prize by the International Tuberculosis Congress last year in Berlin in a competition in which 85 prize essays were presented from all over the world.

When I see the statement that phthisis is not curable even when discovered at an early stage, put forth seriously by my anonymous reviewer, I throw down the pamphlet in despair. One can not argue further with such dense ignorance. It is equal only to the assertion of another medical light among the antivivisectionists, that brain tumors can not be located outside the motor area.

A CASE OF ACUTE BRONCHITIS, FOLLOWED BY COLLAPSE OF THE RIGHT LUNG WITH A SUBCUTANEOUS EMPHYSEMA.

By N. W. BROWN, M. D., of Youngstown, Ohio.

To the Editor of the Philadelphia Medical Journal.

Subcutaneous Emphysema following Bronchitis, being of such infrequent occurrence, I felt that a report of a case, of which I had charge during part of January might be of interest.

Friday afternoon, January 11, 1901, I was called to see a little girl seven years of age, who, I was informed, was suffering with a sore throat.

Upon arriving, my attention was at once attracted by the respiratory efforts, which were rapid and labored. With each inspiration there was dilatation of the alae nasi, and contraction of the muscles of the neck. Previous history! This was good, the mother stating that the child had never been sick before in her life. The present trouble began two days before I was sent for. Upon examination I found her temperature to be 100 3-5, (1.30 P. M.); pulse 142; cough dry and hard; no expectoration; face flushed; tongue moist and heavily coated with white fur; voice almost gone. No pain anywhere except on the left side of the neck in the region of the larynx. From the symptoms and the knowledge that diphtheria was prevailing in the city at the time, I was led to suspect this trouble, but after a careful examination of the throat along with a bacteriological examination I was compelled to dismiss my suspicion. Vomiting had been a prominent symptom. The stomach was very irritable, all food being promptly ejected.

Careful inspection and palpation of the larynx failed to elicit anything such as peri-pharyngeal or laryngeal abscesses.

Percussion and palpation of the chest also, were void of any result, but on auscultation, signs of a beginning bronchitis were noticeable.

January 12: Temperature 100 1-5; pulse 136; respirations 38; vomiting almost ceased. Except for paroxysms of coughing the patient passed a fairly good night. No symptoms of any trouble in the chest, except an acute bronchitis which was rather severe.

January 13: General condition much improved. Cough painless and less frequent. Pulse 132; temperature 100 2-5; respirations 35. Thirst great.

January 14: Breathing easier, respirations 33; pulse 130; temperature 100. Expectoration viscid and yellow and profuse. Coating on the tongue less marked. Patient rested well during the night.

January 15: General condition much improved. Child playful. Respiration 30; pulse 120; temperature 100; expectoration free. With the exception of two severe paroxysms of coughing, rested well during the night. While

taking the temperature in the right axilla, I noticed a fullness in the infra-clavicular space. Upon drawing the arm backward this fullness still remained. Upon further examination, it was found to extend over the chest to the mammary line, in front, around to within three inches of the spine, and down to the lower border of the ribs.

On palpation, marked crackling was obtained. I immediately made up my mind I had a subcutaneous emphysema to deal with; but the question with me was, from where did this air escape. I could get no history of any injury, and although, on previous days, I had examined the throat for an abscess, I could find none. The left lung was hyper-resonant, but on account of the emphysema over the right side, I was unable to detect anything.

January 16: Child passed a restless night, respiration becoming again frequent and labored, as on my first visit. Pulse 142; respirations 41; temperature 100 4-5. Expectoration slightly lessened.

On inspection and palpation I found that the emphysema had extended over the chest, abdomen and back, though not so marked as it had been.

A compensatory emphysema had developed in the left lung. The right lung did not fill up as it should, with each inspiration, and gave signs of collapse. There was no retraction of the epigastrium or intercostal spaces.

January 17: General condition, worse. Pulse 135 and weak; temperature 100 2-5; respirations rapid; lips slightly cyanosed. Child stupid and drowsy. Physical signs the same.

January 18: Child very restless during the night. Dyspnea greater; temperature same as on previous day. Pulse 150 and weaker.

Sputa purulent. About 8 P. M. I was called to meet another physician in consultation, whom the family called. At this visit a gangrenous odor was detected on the breath. Death took place two hours later. No autopsy was allowed. The temperature in this case, at no time of the day, could be found to be over 101; nor did the emphysema involve the tissues about the neck to any extent. The conclusion arrived at by three other physicians who saw the case, and myself is, that the air escaped through the cellular tissue in the neck, due to a rupture of the sub-pleural tissue, and thence following up along the trachea or sheaths of the vessels.

TUBERCULAR ABSCESS OF THE THIGH.

By H. L. UHLER, M. D., of Marion, Ohio.

To the Editor of the Philadelphia Medical Journal.

About the 1st of July, 1900, H. W., aged 28, presented himself at my office for an examination of his leg. There was no tuberculous nor specific history. The leg had been troubling him for about one year past. The left thigh was much swollen, and the leg below the middle of the thigh was edematous, and the skin red and scaly, resembling an eczema. It was not very painful, but under the quadriceps could be felt what was apparently a localized collection of fluid. Temperature at no time raised more than 1-5 to 2-5 above normal. He seemed somewhat pale, a sort of superficial anemia. His weight had decreased a few pounds in the preceding year, during which the trouble had been manifest.

I diagnosed tubercular abscess. After watching the matter closely for a time, I punctured it with a clean exploring needle under aseptic precautions. I obtained nothing but blood. Then I changed my diagnosis to possible sarcoma. After 3 months further waiting, I again explored it with the needle and obtained characteristic tubercular pus. (In the meantime he had been under the care of an Osteopath.)

This time I made an incision and packed it with iodoform gauze, and waited. In a few days it was evident that something further must be done, and I made a free incision, some 10 or 11 inches long, and curetted out a large quantity of caseous material, some of it coming out in pieces as large as my thumb. There was no localization of process, but the entire fascia covering the rectus and a large portion of the lower half of the vastus externus was found to have been curetted away. This left the striae of these muscles entirely bare. The fasciae dipping in between the muscles had been involved at some points, and it was necessary to dip in after these foci with a small sharp uterine curette. I left the whole length of this large wound open and watched every day for other spots of like

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Laudable Hospital Work.—The general public rarely appreciates the value of hospitals unless they are confronted with the necessity for the service of a hospital by such a catastrophe as occurred in Philadelphia on the night of August 5th. If State officials and Philanthropists could have been eye witnesses of some of the untiring efforts on the part of hospital authorities to relieve the pain and suffering occasioned by the gasoline explosion which occurred on Locust street, there possibly would no longer be any necessity for a cry for appropriations and donations. Both the Pennsylvania and Jefferson Hospitals are to be congratulated for their efficient work. It is stated that 14 cases were admitted to the Pennsylvania Hospital, and almost three times that number to the Jefferson Medical College Hospital. The suddenness and pressure of the work requisite for the treatment of those with minor injuries prevented an exact tabulation of the patients treated in the accident ward, but not kept in the hospital, and it is believed that in Jefferson Hospital alone these cases would amount to between 50 and 60.

Money for York Hospital.—A York resident, whose name is withheld, has left the York Hospital \$40,000, payable at his death.

The Lackawanna County Medical Society held its monthly meeting at Scranton, July 8th. Dr. W. M. Reedy presided.

Vital Statistics of Philadelphia for the week ending August 3, 1901:

Total mortality	474	Cases.	Deaths.
Inflammation of the appendix 4,

NEW YORK.

Wycming County Medical Association.—The following officers were elected at the meeting held at Warsaw, N. Y., July 9, 1901: President, Dr. Carl C. Mann, Warsaw; vice president, Dr. P. S. Goodwin, Perry; secretary and treasurer, Z. G. Truesdell, Warsaw. A resolution was also passed adopting by-laws in conformity with those of the New York State Medical Association. The following gentlemen were elected fellows: Z. J. Lusk, Warsaw; L. C. Broughton,

character, and for several days in succession was rewarded by finding more. I always everted these places thoroughly and after a week had no further use for the curette. I did not close the wound for nearly 3 weeks and then only by means of adhesive strips. The patient's temperature continued normal for 11 days, when he was allowed to sit up, when his temperature went up to 104 in 12 hours. This was the beginning of an acute nephritis which lasted for ten days, and subsided. After about a week of quiet he was again permitted to get up and the nephritis returned with double severity. At this time he became so blind that he could not distinguish any person 10 feet away. During this attack he exhibited the most marked edema I have ever seen in this condition. On skimmed milk steadily persevered in, and later followed by Ferri Tinct, he recovered. At this writing the leg is well, he is out of the house, has gained probably 15 or 20 pounds in weight, and his color is better than it has been for 2 years to my certain knowledge. This condition seems to be very rarely observed, in fact so little, that I wrote to Dr. Senn in regard to it. In his Principles of Surgery is the only account of the malady I can find, and only the history of 2 cases. I imagine from Dr. Senn's reply to my inquiry on this subject that he has seen very little of it. This apparent rarity is my principal reason for writing you so extensive an account of this case. I think that the plan of leaving the wound open was an excellent one, as it enabled me to at once notice the recurrence of infection.

THE USE OF BOVINE TUBERCULIN.

By CLEMENT A. PENROSE, M. D., of Baltimore, Md.
To the Editor of the Philadelphia Medical Journal.

Since Professor Robert Koch's recent address before the British Congress on Tuberculosis, London, July 23d, there has been much controversy concerning the identity of the human with the bovine tubercle bacillus.

The idea has occurred to me while reading this address, that much light would be thrown on the matter if injections of tuberculin prepared from the bovine tubercle bacillus were contrasted with those prepared from the human tubercle bacillus, in their effects on persons afflicted with tuberculosis. I can find no evidence in the literature that tuberculin has ever been made from bovine bacillus and tried on human beings, a very simple thing to do.

Steps have been taken by me to obtain this tuberculin, and I desire you to publish this as a preliminary announcement to some subsequent work on this subject.

Whooping Cough; Prognosis of Hospital Cases; Statistics of the Hospital des Enfants Assistés, from 1890 to 1900.—André Morraisse (*Gaz. Heb. de Méd. et de Chirur.*, May 26, 1901, 48me. Année, No. 42): (*Paris Thesis*, 1900-1901, No. 309). Whooping cough in private practice is usually benign, the mortality seldom rising above 1%. This low mortality is evidently the result of the hygienic conditions in which the disease develops. Hospital cases, on the other hand, badly on account of the poor physical condition of the patients, the crowding and the hospital infections. Paris hospitals have a mortality of 25% to 30%. In the hospital des Enfants Assistés, the mortality in 10 years has been 36% in a total of 825 cases. Tuberculosis and bronchopneumonia have been the principal causes of fatal issue. The results reported by Morraisse from the hospital des Enfants Assistés are due to the immediate isolation of the affected children who develop complications, the monthly disinfection following all infections and the antiseptic routine to which the personnel of the hospital is subjected.

[J. M. S.]

Thyroiditis With Mumps.—J. Simonin reports a case of infectious parotitis in a man of 21, with marked glandular involvement, all the lymphatic glands of the neck being enlarged. On the fourteenth day left sided orchitis developed. On the twenty-fifth day thyroiditis appeared, with swelling of the thyroid, tachycardia, and a tremor of the hands. This lasted about two weeks. The thyroid gland was much enlarged. The goiter, palpitation, and tremor suggested an abortive attack of Graves' disease. Thus far, the patient has kept well. Simonin will watch him for some time, to see whether any signs of exophthalmic goiter appear. (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, April 25, 1901, No. 13). [M. O.]

Castile; A. C. Way, Perry Centre; W. B. Blackmer, Pike, Alternates; L. H. Humphrey, Silver Springs; G. S. Skiff, Gainesville; P. S. Goodwin, Perry; C. C. Mann, Warsaw. The next meeting will be held at the Walker House, Silver Lake, N. Y., on Tuesday, September 24, 1901.

Dr. Julius Ullman, of Buffalo, sometime ago was appointed instructor in clinical medicine and assistant in the bacteriological laboratory at the University of Buffalo. Through oversight in preparing copy for the printer, Dr. Ullman's name was omitted from the college announcement for 1901.

Information Wanted Concerning Joseph Dyas, who was last heard from at Dayton, Ohio, on June 22d. Any one who has seen him since this date will confer a favor on his family by communicating with the *New York Medical Journal*.

The Chautauqua County Medical Society held its annual meeting at Chautauqua, July 9th, at which the following officers were elected for the ensuing year: President, E. A. Scofield, of Bemus Point; vice-president, N.E. Beardsley, of Dunkirk; secretary, C. A. Ellis, of Sherman.

Dr. Margaret A. Cleaves, of New York, has recently been appointed the American editor of the *Journal of Physical Therapeutics*, a Quarterly International Review published at London.

NEW ENGLAND.

Stringent Anti-Spitting Ordinance.—The Boston Board of Health has placed itself on record as being determined to enforce its rules relative to expectoration in public places. The penalty for violating the ordinance is \$100.00.

Dr. Charles W. Page has resigned the superintendency of the Middletown Insane Asylum.

WESTERN STATES.

More Plague in San Francisco.—According to the report of Assistant Surgeon Rupert Blue, of the Marino Hospital Service, dated July 20th, 5 new cases of plague had occurred up to that date in San Francisco. The matter has been treated editorially in this week's issue of the *Philadelphia Medical Journal*.

Dr. Almah J. Frisby, who has recently been appointed on the Board of Regents of the University of Wisconsin, is the first woman in the history of this Board to serve on it.

Wayne County Medical Association.—At the annual meeting of the Wayne County Medical Association held in Richmond, Ind., July 11th, the following officers were elected: President, Dr. H. B. Boyd, of Cambridge City; vice-president, Dr. H. Gable, of Centerville; secretary and treasurer, Dr. S. C. Markley, of Richmond. Following the business there were three papers read, which were as follows: "Enterocolitis," by Dr. Hopkins; "Whooping Cough," by Dr. W. O. Mendenhall, and "The Physiology of the Brain," by Dr. D. W. Stevenson.

Enteric Fever in Chicago.—Reports indicate that an unusually fatal epidemic of enteric fever prevails in Chicago. It is stated that there are 38 cases in the County Hospital, of which 6 died in one day.

Byron Springs Sanitarium Destroyed by Fire.—The hotel and cottages forming the famous Byron Springs, Cal., were completely destroyed by fire on July 25th. Fortunately the fire occurred during the day and there was no loss of life. The losses of the guests will be quite heavy, few having saved more than a little wearing apparel.

SOUTHERN STATES.

Vaccination in Baltimore.—It is stated that Health Commissioner Bosley proposes to inaugurate a vigorous crusade against smallpox on August 15 by insisting upon a general vaccination of Baltimoreans.

Anthrax has appeared among cattle in Kent county, Maryland.

Washington is now free from smallpox. The quarantine hospital was closed on July 7.

Dr. Lee Wood, formerly of Mississippi, but more re-

cently of Abbeville, La., died at Warsaw, Ark., June 14, after a prolonged illness. Dr. Wood graduated at the University of Tennessee, Nashville in 1890.

Dr. H. B. Horlbeck Dead.—Dr. Henry Buckingham Horlbeck, for 20 years health officer of Charleston and a former president of the American Public Health Association, died at Charleston, S. C., on August 2d. He left directions for his body to be cremated and it was shipped to New York. Dr. Horlbeck was born in Charleston, S.C., July 15, 1839. He was educated at the Classical School of Prof. A. Sachtleben. In 1856 under the direction of his father, Dr. Ellis Horlbeck, he began the study of medicine. He attended three courses of lectures at the Medical College of the State of South Carolina and was graduated March 15, 1859. Dr. Horlbeck was house surgeon to the Roper Hospital, from April, 1859, to April, 1860. He then visited London and Paris, attending the lectures of V. Beau, Trousseau, Chassaignac and Ricord. He was commissioned surgeon of the First Regiment, South Carolina Regulars, Col. William Butler, Confederate Army, September, 1862, and was in active service during the bombardment of Fort Sumter and Fort Moultrie, at Battery Wagner, James Island and at the battles of Averysboro and Bentonville. He was mustered out of service April 9, 1865. Dr. Horlbeck had been health officer of Charleston since 1881 and secretary of the Board of Health of Charleston since 1886. He took a great interest in perfecting a quarantine service for the protection of Southern ports against yellow fever and succeeded in obtaining an appropriation from the Legislature of South Carolina, which resulted in the efficient plant in use in Charleston harbor. Dr. Horlbeck was a member of the South Carolina Medical Association, American Public Health Association, vice-president of this association, 1890-91, and was elected president in September, 1896, at the convention held in Buffalo. He was chairman of the board of commissioners of the City Hospital in 1886; member of Ancient Battalion Artillery and the Agricultural Society of South Carolina, of which he was president in 1880. Dr. Horlbeck was the author of many valuable contributions to medical journals and issued annual reports from the Charleston Health Department since 1880.

CANADA.

(From Our Special Correspondent).

The Canadian Medical Association.—The annual meeting of this society will be held at Winnipeg on August 28th, 29th, 30th and 31st. The address on surgery will be delivered by Dr. O. M. Jones, of Vancouver, and the address in medicine by Dr. J. R. Jones, of Winnipeg.

Meeting of the Ontario Medical Association, held at Toronto, June 19th and 20th. (Continued). Discussion on Gastric Ulcer.—Medical Aspect.—This was introduced by Dr. R. D. Rudolf, Toronto. In opening the discussion from a medical point of view, he gave a short historical sketch of the chief literature on the subject, and said during the last thirty years only one important symptom had been added to those mentioned by previous writers, viz.: the very common occurrence of hyperchlorhydria. Avoiding the consideration of the well-known points on the subject, he propounded five questions in connection with gastric ulcer which seemed to him to specially merit discussion. First, is there any relation between gastric ulcer and cancer? Trousseau believed that an actual antagonism existed between the two conditions, while Lebert considered that 9 per cent. of all gastric cancers so arose, and Rosenheim states that 5 to 6 per cent. of all gastric ulcers became carcinomatous. Clinically, the speaker had never seen a case of simple ulcer in cancer, nor had he seen a case of cancer preceded by ulcer, although such cases undoubtedly occasionally occurred.

Dr. Rudolf had seen pathological specimens illustrating both. Second: Can we diagnose the site of gastric ulcer? This question is becoming more important on account of operations. Ewald states that in 90 per cent. of cases it is impossible to tell whether the ulcer is in the stomach or in the duodenum, and that usually it is hard to diagnose the site of the stomach. Most gastric ulcers occur on the posterior wall, near the pyloric end. The site of the pain and tenderness; the time the pain occurs after food; the position in which the patient is free from pain, and the presence or absence of gastric dilatation may help, but these are very uncertain facts to lean upon. Thus, in Pin-

nel's famous case, mentioned by Abercrombie, where the patient was known to have ulcers near the pylorus, the pain used to occur immediately after taking food. The taking the food may not only mechanically irritate the ulcer, but by stimulating the acid secretion peristalsis may cause pain without touching the ulcer. It must further be remembered that there are sometimes several ulcers present. Third question: Does ergot ever stop gastric hemorrhage? Most authorities recommend ergot without question, but we must remember that the hemorrhage tends to be self-limiting from the lowering of the blood pressure and the forming of a clot, and ergot may interfere with this natural cure by raising the blood pressure. Turpentine and other local styptics have no such objection, and calcium chloride increases the tendency to clotting. Fourth question: Are cases of apparently "cured" gastric ulcer "first-class lives" for insurance? The speaker did not think that they were, because sudden perforation might occur after years of quiescence (he had seen two such cases). Ulcers were apt to relapse or to break out in new places. The severer the symptoms of the ulcer had been at the time, especially the hemorrhage, and the shorter the period since its occurrence, the worse the "life" was. Fifth question: As regards operation; as soon as perforation into the peritoneal cavity be diagnosed, operation should at once be performed; as regards operation where no perforation exists the question was not so easily settled. Severe, uncontrollable hemorrhage might occasionally call for surgical treatment, but the mortality from hemorrhage is surprisingly small, even when this is severe. Dr. Mayo Robson had recently recommended "that after a second bleeding, even during the course of the hemorrhage, if the patient can stand it, or as soon after as his condition will admit, the operation should be done. The speaker was glad to see that his old teacher, Dr. Byrom Bramwell, challenged this advice (*The Lancet*, March 9, 1900, page 687). Operation for the less urgent symptoms of gastric ulcer would occasionally be necessary, but in this direction we should proceed with great caution. Dr. Moynihan, in a recent paper (*The Lancet*, April 27, 1901), gave a summary of all the cases to date in which gastroplasty or gastro-gastrostomy had been performed for "hour-glass stomach." They amounted to thirty-eight in all, and nine of them were fatal, while in many complete relief of symptoms occurred.

Pathology.—This branch of the discussion was led by Dr. H. B. Anderson, Toronto. In his opening remarks he said he would make no reference to ulceration resulting from the breaking down of tubercular foci, syphilitic gummata, or malignant growths, nor of ulceration occurring during the course of acute infective diseases nor resulting from the action of corrosive poisons, but would limit the discussion to a consideration of the commonly designated simple, round, perforating or peptic ulcer. From the similarity in all essential points, however, he included the corresponding ulcer at the lower end of the esophagus and in the first part of the duodenum. From post-mortem statistics the frequency of gastric ulcer was in about 5 per cent. of cases, cicatrices being found about three times as often as healed ulcers. From his own experience at autopsies in Toronto he was sure that gastric ulcer did not occur in Ontario as frequently as indicated by the above figures.

The condition occurred most frequently in adults twenty to forty years of age, but was by no means rare at the extremes of life. The mortality was greater from forty to sixty years of age, no doubt from the lessened reparative power at that period of life. Females were affected more frequently than males, in about the proportion of two to one.

The etiological import of other diseases, especially chlorosis, was dwelt upon. Injury was a factor in rare instances, a statement substantiated by certain data. Occupation, race, climate, habits—all had an indirect influence in some cases, and arterial sclerosis, thrombosis and embolism of the gastric vessels were occasional factors in the etiology of the condition.

All these factors were, however, of secondary importance, and were only active in the presence of an altered condition of the gastric secretion. The localities where this form of ulceration occurred—at the lower end of the esophagus, in the stomach and in the first part of the duodenum—situations exposed to the ac-

tion of the gastric juice, as well as the not infrequent occurrence of postmortem digestion of the walls of the stomach, were strongly suggestive of the importance of this factor and this had received further direct proof from the discovery of the frequent occurrence of a hyperchlorhydria associated with gastric ulcer from a chemical analysis of the stomach contents obtained after test meals. The failure to find this condition in some cases was not proof that it had not existed at an earlier period of the disease, for the hyperchlorhydria might afterwards have been lessened as the result of the greater or less degree of gastritis following in the wake of the ulcer. Ulceration did not occur unless there was a disproportion between the acidity of the gastric juice and the condition of the blood. Normally autodigestion of the walls of the stomach was prevented, not by a simple chemical reaction in which the acid was neutralized by the alkalinity of the blood and fluids in the tissues, but by the vital resistance of the living cells of the part. He did not think there was anything to uphold the bacterial origin of this form of ulcer urged by some authors.

The pathological anatomy of gastric ulcer and its various terminations were discussed and illustrated by specimens. Healing was the fortunate result in the majority of cases. At other times a fistulous communication was formed with the duodenum, colon or the cutaneous surface, or a subphrenic abscess might result. Adhesion to the pancreas, liver, or to the omentum frequently walled the trouble off. Not infrequently, however, peritoneal infection from perforation occurred, and the symptoms might be so intense as to simulate poisoning. Gastrectasia or "hour-glass" deformity from cicatricial contraction at the pyloric orifice, or in the centre of the organ, at times gave rise to serious results. A specimen, showing the development of a carcinoma at the base of an ulcer with a clinical history extending over many years, was presented.

(To be Continued.)

MISCELLANY.

An Interesting Statistic.—According to the latest governmental statistics, each physician in the United States has 655 persons to look to for his support.

A Dangerous Amusement.—"Loop-the-Loop" is the name of a new entertainment which goes further in the way of tempting Providence than anything yet invented. The "Loop" is an immense circle of track in the air. A car on a mimic railway shoots down a very steep incline, and is impelled around the inner side of this loop. Part of this journey, of course, is made "heads down," the people in the car retaining their places by the great centrifugal force. The authorities at Coney Island are said to have prohibited "looping-the-loop" because women break their corset strings in their efforts to catch their breath as they sweep down the incline, and moreover, a young man is reported to have ruptured a blood vessel in his liver. We predict other accidents from this contrivance yet. No person with a weak heart or bad arteries should try it.

Obituary.—Dr. P. C. Mensch, at Collegeville, N. J., July 29th, aged 32 years—S. C. Vankirk, at Grafton, W. Va., July 23rd—Dr. Gilbert E. Palen, at Ocean City, N. J., July 30th, aged 69 years—Dr. Adam Miller, at Chicago, July 29th, aged 91 years—Dr. Stephen Foss, at Brooklyn, N. Y., August 2nd, aged 76 years—Dr. Adam Miller, at Milwaukee, Wis., July 30th, aged 91 years—Dr. Milo B. Ward, at Kansas City, July 28th, aged 50 years—Dr. Joseph H. Osterstock, at Easton, Pa., July 31st, aged 65 years—Dr. Arthur B. Marshall, at Wytheville, Md., August 3rd, aged 46 years—Dr. Geo. W. Dorsey, at Prince Frederick, Md., July 23rd, aged 81 years.

Official List of the Changes of Station and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Hospital Service for the 7 Days Ended July 25, 1901.

- C. E. BANKS, surgeon, granted leave of absence for 3 days from July 25—July 29, 1901.
- C. T. PECKHAM, surgeon, Bureau order of July 17, 1901, relieving Surgeon Peckham from duty at Galveston, Texas, and directing him to report to medical officer in command at Boston, Mass., for duty, revoked; and directed to report to Surgeon G. W. Stoner, Immigration Depot, New York, for duty—July 23, 1901.
- W. P. McINTOSH, surgeon, leave of absence for 1 day under paragraph 178 of the regulations.

- T. H. PERRY, surgeon, to proceed to Martinsburg, W. Va., for special temporary duty—July 23, 1901.
- J. O. COBB, passed assistant surgeon, granted leave of absence for 30 days from July 21—July 22, 1901.
- A. H. THOMAS, passed assistant surgeon, granted leave of absence for 30 days from August 16—July 20, 1901.
- HILLI HASTINGS, assistant surgeon, 2 months' leave of absence granted by Department letter of June 28, amended so that said leave shall be from July 20 instead of July 15—July 20.
- M. H. FOSTER, assistant surgeon, granted leave of absence for 14 days from August 8—July 23, 1901.
- A. J. McLAUGHLIN, assistant surgeon, granted leave of absence for 7 days under paragraph 178 of the regulations.
- M. W. GLOVER, assistant surgeon, Bureau order of July 17, 1901, relieving Assistant Surgeon Glover from duty at Boston, Mass., and directing him to report to Surgeon G. W. Stoner, Immigration Depot, New York, for duty, suspended—July 13, 1901.
- J. D. LONG, assistant surgeon, granted leave of absence for 7 days under paragraph 178 of the regulations.
- P. G. RIERA, acting assistant surgeon, granted leave of absence for 1 month from July 11—July 20, 1901.
- W. A. LUCAS, interne, granted leave of absence for two weeks from July 25, on account of sickness—July 24, 1901.
- L. W. RYDER, hospital steward, granted leave of absence for 15 days from August 5—July 24, 1901.

APPOINTMENT.

- A. H. BARR appointed interne in the Marine Hospital Service for duty at Port Stanton, N. M.—July 22, 1901.

Official List of the Changes of Station and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Hospital Service for the 7 Days Ended July 18, 1901.

- C. T. PECKHAM, surgeon, upon expiration of sick leave of absence, relieved from duty at Galveston, Texas, and directed to proceed to Boston, Mass., and report to the medical officer in command for duty and assignment to quarters—July 17, 1901.
- J. A. Nydegger, passed assistant surgeon, granted extension of leave of absence, on account of sickness, for 30 days from July 9—July 6, 1901.
- H. W. WICKES, passed assistant surgeon, granted leave of absence for 27 days from July 16—July 8, 1901.
- J. B. GREENE, passed assistant surgeon, directed to proceed to Point Pleasant, N. J., for the physical examination of keepers and surfmen of the Life Saving Service. Upon completion of said duty to rejoin station at Washington, D. C.—July 16, 1901.
- CARROLL FOX, assistant surgeon, to report to the medical officer in command at Port Townsend, Wash., for temporary duty—July 11, 1901.
- E. D. LORD, assistant surgeon, relieved from duty at the Immigration Depot, New York, N. Y., and directed to proceed to Galveston, Texas, and assume command of the service, relieving temporary Acting Assistant Surgeon Wm. Kellier—July 17, 1901.
- M. W. GLOVER, assistant surgeon, relieved from duty at Boston, Mass., and directed to proceed to New York, N. Y., and report to Surgeon G. W. Stoner, Immigration Depot, for duty—July 17, 1901.
- C. WILLIAMS BAILEY, acting assistant surgeon, granted leave of absence for 7 days—July 6, 1901.
- J. P. C. FOSTER, acting assistant surgeon, granted leave of absence for 40 days from July 31—July 10, 1901.
- S. GOMEZ, acting assistant surgeon, granted leave of absence for 30 days from July 15—July 12, 1901.
- R. L. McNEER, acting assistant surgeon, relieved from duty at Baltimore, Md., and directed to proceed to Cape Charles quarantine and report to Assistant Surgeon C. W. Wille for duty and assignment to quarters—July 17, 1901.
- M. A. SAFFORD, acting assistant surgeon, granted leave of absence for 14 days from July 17—July 6, 1901.
- W. L. STEALINS, hospital steward, granted leave of absence for 20 days from August 12—July 15, 1901.
- A. M. Roehrig, hospital steward, granted leave of absence for 16 days from August 17—July 15, 1901.
- J. V. LAGRANGE, hospital steward, granted leave of absence for 30 days from August 2—July 15, 1901.
- E. B. SCOTT, hospital steward, granted leave of absence for 1 day—July 8, 1901.
- M. H. WATTERS, hospital steward, relieved from duty at St. Louis, Mo., and directed to proceed to Washington, D. C., and report at the Bureau for duty—July 11, 1901.

APPOINTMENTS.

- H. J. BEARD appointed interne for duty at Evansville, Ind., July 17, 1901.
- M. H. ROSS appointed interne for duty at Cairo, Illinois, July 12, 1901.

Changes in the Medical Corps of the Navy, Week Ended August 3, 1901.

ASSISTANT SURGEON J. W. BACKUS, detached from the Vermont and ordered to the Atlantic Station, August 16—July 30.

ASSISTANT SURGEON F. A. ASSERSON, detached from the Naval Hospital, New York, and ordered to the Asiatic Station, August 16—July 29.

SURGEON S. H. GRIFFITH, relieved as recruiting officer at Buffalo, N. Y., and ordered to continue other duties—Aug. 1.

Official List of the Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Hospital Service for 7 Days Ended August 1, 1901.

- FAIRFAX IRWIN, surgeon, granted leave of absence for 21 days from August 7—July 18, 1901.
- J. O. COBB, passed assistant surgeon, Bureau letter of July 22, 1901, granting Passed Assistant Surgeon Cobb leave of absence for 30 days from July 24, amended so that said leave shall be effective July 25—July 31, 1901.
- C. P. WERTENBAKER, Passed Assistant Surgeon, to proceed to Camp Fontainebleau and adjacent coast towns as inspector—July 20, 1901.
- J. B. GREENE, Passed Assistant Surgeon, relieved from temporary duty at Washington, D. C., and directed to proceed to New York (Stapleton) and report to medical officer in command for duty and assignment to quarters, relieving Assistant Surgeon Tallaferra Clark—July 20, 1901.
- TALLAFERRO CLARK, Assistant Surgeon, upon being relieved by Passed Assistant Surgeon J. B. Greene, to proceed to Immigration Depot, New York, N. Y., and report to Surgeon G. W. Stoner, for duty, relieving Assistant Surgeon J. D. Long—July 20—1901.
- W. A. KORN, Assistant Surgeon, granted leave of absence for 1 month from August 12—July 29, 1901.
- J. D. LONG, Assistant Surgeon, upon being relieved by Assistant Surgeon Tallaferra Clark, to proceed to Manila, P. I., and report to Chief Quarantine Officer for duty—July 29, 1901. Granted leave of absence for 2 days—July 30, 1901.
- L. C. BEAN, Acting Assistant Surgeon, granted leave of absence for 30 days from August 2—July 29—1901.
- R. Y. HARRIS, Acting Assistant Surgeon, granted leave of absence for 15 days from August 12—July 31, 1901.
- H. McI. MARTIN, Acting Assistant Surgeon, granted leave of absence for 30 days from August 1—July 31, 1901.
- T. V. O'GORMAN, Hospital Steward, granted leave of absence for 60 days on account of sickness, to take effect on date of departure from station—July 26, 1901.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended August 3, 1901.

SMALLPOX—United States and Insular.

GREAT BRITAIN.

Jacksonian Prize.—Mr. McAdam Eccles, M. S., F. R. C. S., Eng., has been awarded the Jacksonian Prize of the Royal College of Surgeons of England, and has been elected a Hunterian Professor for 1901-1902. The subject of his essay for the prize was "The Diagnosis and Treatment of the Diseases caused by and connected with Imperfect Descent of the Testicle."

Mr. J. W. Dowden, M. B. C. M., F. R. C. S. Ed., has been appointed Assistant-Surgeon to the Edinburgh Royal Infirmary.

Sir Francis Laking, Physician in Ordinary to the King, has been elected consulting physician, and **Mr. T. Pickering Pick, F. R. C. S.,** consulting surgeon, to the Victoria Hospital for Children, Chelsea.

CONTINENTAL EUROPE.

Gilles de la Tourette, the eminent alienist and the distinguished pupil of Charcot, has himself become insane, and is in an asylum.

The Nudity Cure.—There is a village in Austria near the Adriatic, states the *Medical Age*, where the nudity cure is practiced. The debilitated, neurasthenics, the tired, etc., can go there and, in the costume of Adam, expose their individuals to the air, the sun's rays, or the rain. Thickets are carefully arranged so as to cut off all view of the patients; a hat and short trunks only are allowed; the sexes are separated. Baths, massage, gymnastics, and games are indulged in, and a strict vegetarian diet completes the treatment.

The French National Periodical Congress of Gynecology, Obstetrics and Pediatrics will meet this year at Nantes under the general presidency of Dr. Sevestre, of Paris, who will also preside over the section on pediatrics. Dr. Segond will be the president of the section on gynecology, and Professor Queiral, of Marseilles of the section on obstetrics.

A New Journal.—An adjourned meeting of members of the medical profession practicing obstetrics and gynecology, states *The Lancet*, was held in London on July 24th, under the presidency of Sir John Williams, at which it was unanimously resolved to establish a new Journal, to be called *The British and Colonial Journal of Obstetrics and Gynecology*, and to raise the funds required for its publication by the formation of a limited liability company.

Dr. Bureau, of the Museum of Natural History, Professor of Botany at the University of Paris, has recently been elected a member of the French Academy of Medicine.

Dr. Weill has been appointed Professor of Pediatrics at the University of Lyons.

Humor at the British Congress on Tuberculosis.—According to the *London Chronicle* there were two distinct sensations at the opening of the British Congress on Tuberculosis. One was when the American delegate, Prof. Osler, rapped out a good round oath, with an apology of course to the Duke of Cambridge and to the ladies in the gallery. He contrasted the altruistic attitude of the members of the congress with the egotistic attitude of the great American trusts, and said the motto of the one was "Pro bono publico," while the other adopted the motto: "D—n the public." The other sensation was when Prof. von Schrotter, the representative of Austria, described the Berlin Congress on Tuberculosis of 1896 as exceeding "the most sanguine expectations."

A Virchow House.—The Medical Society of Berlin has decided to erect a Virchow House as a permanent memorial of its honorary president, Professor Rudolph Virchow, the 50th anniversary of whose birthday will soon be commemorated. Considerable money has already been placed at the disposal of the society for the completion of its plan. The Paris Anthropological Society, upon invitation, will be present at the celebration, and will present Professor Virchow with a large gold medallion.

Virchow on Koch.—Prof. Rudolph Virchow's eightieth birthday will be celebrated in Berlin on Saturday, October 12, when he will personally receive delegates with congratulatory addresses from various scientific bodies, foreign as well as German. Prof. Virchow is not without a certain youthful vigor, especially in thought. When asked the other day what he thought of Koch's latest pronouncement on consumption he said: "Koch is not a Pope. One cannot say because of his views the thing is settled; Roma locuta est (Rome has spoken)."

Society Reports.

Proceedings of the School for Health Officers, held in Burlington, Vermont, from July 8th to July 11th, inclusive.

The Health Officer's School opened with an attendance of about 150, representing nearly all sections of the State. Dr. C. S. Caverly, president of the State Board, called the meeting to order and gave a brief review of health legislation in the State of Vermont. He showed the difference in the prevalence of diseases before and after the establishment of the State Board of Health and the enactment of this public health law. The Board was welcomed by Mayor Hawley, Gov. Stickney, and Hon. J. A. DeBoer, of Montpelier.

The second day opened with about the same attendance as the previous evening. The first speaker was Col. Joel C. Baker, of Rutland, who exhaustively treated the subject of laws relating to public health. This paper was discussed by Hon. D. J. Foster, of Burlington, Drs. Holton, of Brattleboro, Grout, of Waterbury, Newton, of Benson, and Sanborn, of New Haven.

H. L. Stillson, of Bennington, read a paper on the duties and responsibilities of health officers, which was discussed by Dr. L. M. Greene, of Bethel.

Dr. W. N. Platt read a paper on sanitary legislation. The paper was discussed by Dr. W. S. Hubbard and Dr. W. D. Huntingdon.

Dr. D. D. Grout next read a paper on "The Relation of Animal Diseases to Public Health." He calls attention to the common causes of infectious diseases, and the transmission of animal disease to man. Of all domestic animals none are so intimately or closely related to the human race as the cow. Grout gives a tabular form of diseases of domestic animals that are known to be communicable to man. They are: (1) Glanders and farcy in horses, etc.; (2) canine madness, rabies in dogs, cats, etc.; (3) malignant anthrax in all domestic animals; (4) tuberculosis in all animals; (5) malignant cholera in all animals; (6) milk-sickness in animals; (7) small-pox in all animals and fowls, (8) diphtheria in animals; (9) scarlet fever in various animals, (10) plague, which is a disease so common to man, monkey and rodents. A brief discussion of the mode of transmission of these diseases is given. Tuberculosis is a disease which affects nearly all our domestic animals, and tuberculous cattle are especially to be dreaded, since they furnish so much food for the consumption of men. In the Northern States from 5 to 8 per cent. of the cattle suffer from tuberculosis, and in some localities 50 per cent or more are affected. The question whether the bacillus which produces the disease in man is identical with that found in cattle is one of very great importance, for upon the affirmative settlement of the question rests the possibility of transference of the disease from animals to man and vice versa. It is generally believed that the bacillus found in man and cattle are the same. There have been many instances that point to the conclusion that the disease has been transferred from cattle to man, and Grout thinks there can be no question that the bacillus is the same if the disease can be carried from one to the other.

Regarding the proportion of infection from tuberculosis, he considers that more deaths occur among the human race than among animals, but that there are far more dairy cows infected with tuberculosis in proportion to their number than in the human family. He believes that the high natural temperature has much to do with this lower death rate in cows, for the tubercle bacillus requires for its growth, multiplication and pathogenicity, a temperature above that of the normal body, and the raised temperature of the human subject that is pathognomonic of the growth of the tuberculous masses is the normal bovine temperature. Consequently, tubercle will grow in the cow without any disturbance of her normal temperature, and the train of consequences that follows the effects of increased bodily heat does not occur in the cow from an invasion of tuberculosis, and therefore the progress goes on in the animal, and unless other morbid conditions supervene to increase the bovine temperature, the tubercle does not break down and cause sepsis, which is always the cause of

death where the primary disease is tuberculosis. This he considers a good reason for the apparent good health, good flesh and prime condition of many cattle that are tuberculous. Grout regards nodulation (nest-building) as the first step in tuberculosis. These may remain in a dormant or latent state for a very long time, and their spreading is undoubtedly due to an alteration of the general health which lowers the power of resistance of the patient. Grout considers the removal of diseased animals the essential requirement in the prevention of disease. He thinks the use of the tuberculin test in the early stages of great advantage, especially in cattle. As to the treatment of infected animals, he advises that animals without outward signs of disease might be fattened for the butcher and inspected, and if found to be tuberculous, they are to be killed. After all tuberculous animals have been removed the stables should be disinfected, and the remaining healthy animals retested with tuberculin. All animals introduced into a herd should be examined, tested, and found to be sound beforehand.

Regarding the contamination of milk he calls attention to the fact that not only is milk drawn from a cow with a tuberculous udder likely to contain the bacillus, but mentions other possible sources of contamination. In tubercular animals the disease in a large proportion exists in the gastrointestinal tract, and the bacilli are thrown off in the feces which may adhere to the animal when it lies down, and this by a careless milker may be brushed off into the milk. The feces also becomes dried, the dust of the stable is loaded with the germs, and he considers it doubtful if milk ever leaves the stable where the disease exists without containing tubercle bacilli. He also calls attention to the possible contamination of milk after it is drawn from the cow. In conclusion he advises that legislation is needed that will require the tuberculin test of every animal in the state, and that dairymen should be educated to see that it is not for their interest, to say nothing of the interests of the consumers of their products, to keep their cattle in unhygienic surroundings, such as small, dark, damp and unventilated stables, and that a law requiring the rigid inspection of dairies should be enacted.

This paper was discussed by Dr. F. A. Rich and Dr. C. W. Peck. Dr. Peck called attention to the fact that 5000 people die annually from tuberculosis in Vermont, and 6000 children under 6 years of age are killed by bad milk.

E. B. Moore then spoke on the subject of milk supplies, which was discussed by Drs. P. P. White, G. G. Marshall and W. H. Vincent.

At the evening session J. H. McCollum gave an address on smallpox eruptions, illustrated by copious stereopticon views. Drs. E. D. Ellis, of Poultney, and Dr. R. T. Goss, of Hartford, and Dr. J. W. Copeland, of Lyndonville, illustrated the progress made in stamping out smallpox in their respective towns recently.

The first paper of the morning session was on plumbing by W. P. Gerhard. He called attention to the great advance made in plumbing, but thinks a simpler system is needed which will be more effective and less costly. Following this a paper on vital statistics was read by Dr. C. L. Wilbur. This paper was discussed by Drs. Allen, Caverly, Holton and Hon. C. W. Crowell.

Dr. H. H. Stone read a paper on the value of blood examination, which was followed by a paper on "The Value of Our Laboratory to the People," by Dr. M. J. Wiltse. This paper was discussed by Dr. S. E. Maynard, Dr. John Egan, Hon. E. D. Proctor and Dr. F. Fletcher.

Prof. W. T. Sedgwick mentioned great epidemics directly traceable to the water supply. Mr. C. P. Mont opened the discussion, which was continued by Drs. Avery, Philip, Sanborn and Bront.

Prof. Sedgwick called attention to the fact that destruction of sewage was more fundamental than that of procuring good water. Lantern slides were then used illustrating the different forms and conditions of sewage. The paper was discussed by Drs. Holton, Grout and Sanborn.

Dr. W. L. Hollington then took up the subject of School Sanitation, which was discussed by Drs. Leavenworth, Sanborn, Kent, Hipgood and Osgood.

The Latest Literature.

BRITISH MEDICAL JOURNAL.

July 20th, 1901.

1. A Clinical Lecture on Total Extirpation of the Prostate for Radical Cure of Enlargement of that Organ; With Four Successful Cases. P. J. FREYER.
2. The Treatment of Stammering (and "Lalling"). H. GRAHAM LANGWILL.
3. On Edematous and Erysipelatous Anthrax. JOHN HENRY BELL.
4. A Case of Multiple Malignant Pustules (Anthrax). R. LAWFORD KNAGGS.
5. A Case of Anthrax with Extensive Meningeal Hemorrhage. JOSEPH C. STURDY.
6. The Danger of Anthrax from the Manipulation of Horse-hair, and its Prevention. ALEXANDER SCOTT.

1.—P. J. Freyer, in discussing the radical cure of enlargement of the prostate, states that until recently partial prostatectomy by the suprapubic route was the most commonly applicable and most satisfactory of all the operations. After this operation, however, the expulsive power of the bladder is usually lost. Freyer thinks that the trouble lies in the fact that pressure is still exerted on the urethra by the enlarged lateral lobes. The author then reports 4 cases in which he has performed a total prostatectomy by the suprapubic route with the most satisfactory results, and reproduces photographs of the organs after removal. Each is found to be encapsulated and contains several smaller tumors also encapsulated. In each case the growth was an adenoma. Where the two lateral lobes are removed separately the ejaculatory ducts are left uninjured. When the gland is removed as a whole, however, the author is uncertain what injury is done to the ducts. This is thought to be a matter, however, of little importance when the age of the patient is considered. When the gland is enucleated out of its sheath there is only a small amount of hemorrhage, and this can readily be controlled by hot irrigation. The large cavity left after removal of the prostate quickly contracts. One of the most satisfactory features of the operation is the fact that restoration of the expulsive power of the bladder is obtained. In each of the author's cases the patient was able to retain the urine for a number of hours. [J. H. G.]

3.—John Henry Bell reports six cases of edematous and erysipelatous anthrax. This condition is so named on account of its resemblance to erysipelas, and not that it is a compound of erysipelas and anthrax. The condition begins with a pale swelling, soft and without pain. It is only after several days and marked development that vesicles and eschar form, notably on the eyelids, but at the onset the skin is smooth and has no trace of pimples. The general symptoms are negative. The freedom from pain and distress is remarkable. The pulse is not greater than normal, nor is the temperature above that of health. The local symptoms are the extensive edema which may extend from the scalp to the pubes with much swelling. In slight cases there is no redness, vesication or eschar; in severer cases there is much redness, late vesiculation and eschar, or gangrenous appearance of the skin. In none has there been pain, only tightness from stretching of the skin. Of six cases here recorded, three were fatal. As to treatment, it is evident that incision, cautery, or caustics were not suitable for the diffused inflammatory form. The writer believes that the most promising method of treatment is the intravenous injection of non-toxic germicides. [T. L. C.]

4.—R. L. Knaggs reports a case of multiple malignant pustules (anthrax). In a groom of 20 years, treatment of excision of the pustule was followed, also the symptoms promptly disappeared. The writer believes that this result may be counted upon if the bacilli have not penetrated the lymphatics and been carried on beyond the focus of the disease. Infection of the resulting wound by bacilli from the sore which is being cut out cannot be a really serious danger. The writer has seen many pustules, but no recurrence in the wounds. [T. L. C.]

5.—Joseph C. Sturdy reports a case of anthrax with meningeal hemorrhage. The patient was a wool-sorter of 33 years and complained of a swelling on his neck three

inches above the clavicle, on the right side. The adjacent glands were not enlarged. The condition was recognized as anthrax. The swelling was excised. On the following morning he suddenly became blind, accompanied by pain in the head, vomiting, and in half an hour he was unconscious and very restless. At 5.30 in the afternoon, the temperature in the axilla was 99.7° and in the rectum 102.2°. The violence of the symptoms continued, and he died late in the same night. Bacteriological examination of the blood, pleural and peritoneal fluids, revealed the presence of the anthrax bacilli. [T. L. C.]

6.—Alexander Scott discusses the danger of anthrax from the manipulation of horsehair, and its prevention. He believes that all the workers should wear overalls; that no one with any cut or abrasion of the skin should be allowed to work unless the wound can be absolutely protected from contamination; that all workers should wash themselves frequently, especially before taking food; that all cases of illness, especially if connected with any swelling or boil, should be immediately intimated to the manager, so that the other workers similarly exposed may be warned of their danger. He believes that the bales of horsehair should not be handled except in a wet state, which will prevent dust from arising. He further advises that the hair should be boiled for half an hour in order to cleanse it, and, if necessary, that disinfectant agents be added. Care should be taken that all dust and residue be carefully burned. [T. L. C.]

1.—Savill delivered a lecture on "The Pathology of Hysteria" at the West End Hospital for Diseases of the Nervous System, Welbeck street, London. The author states that there is only one tenable explanation for the production of hysterical attacks, namely that the same anatomical part of the nervous system is the seat of the lesion, and that this damage is of sudden onset and disappears with equal rapidity. He further emphasizes that this anatomical change is a vascular one. This theory is based upon purely clinical manifestations of the disease, such as hysterical syncope, the hysterical diathesis, and upon the causes of hysteria. It is highly probable that the nervous apparatus of the splanchnic area (abdominal sympathetic) is very susceptible in hysterical individuals, and is easily influenced by emotional disturbances, such as grief, fear, and anger. This nervous derangement of the splanchnic area, which may give rise to hysteria, induces a dilatation of the blood vessels and cerebral anemia immediately follows. Syncope and even convulsions may be produced by this cerebral anemia. He defines hysterical diathesis as "a peculiar condition of the nervous system, inherent in the individual and for the most part inherited, consisting in its psychological aspect of the want of self-control and emotional instability, and in its physical aspect of a tendency throughout life to the development of various sensory, motor, visceral, and neuro-vascular disturbances, not connected with any definite organic lesion by our present means of investigation." The causes of hysteria are classified as predisposing, contributory or exciting, and those which may determine the attack. There is ample reason for believing that the ilio-hypogastric nerve is the de-

pressor nerve of the abdominal sympathetic, which, when irritated, in those individuals who show a hysterogenic zone along its distribution, produces dilatation of the blood vessels in the splanchnic area and consequently cerebral anemia, with the development of all the phenomena of an attack of hysteria. Savill promises at some future date to submit further proof to substantiate the theory which he has advanced. [F. J. K.]

2.—W. J. McCardie reports his recent experience with ethyl chloride narcosis and presents briefly the history of 26 cases in which this agent had been used in the performance of minor operations. The longest anesthesia lasted about 16 minutes. In this case a previous anesthetization with chloroform had given rise to serious symptoms. Many of the operations done were for hypertrophied tonsils and adenoids. In one case there developed a peculiar rash during the anesthesia; in another instance great muscular excitement rendered complete anesthesia impossible. This patient was not an alcoholic. In a third case death occurred about an hour after the narcosis. The patient had made a good recovery without any other effects. The postmortem showed advanced disease of the heart and other organs. The condition of the heart was supposed to be the cause of death. It is not thought the chloride of ethyl had anything to do with it, since no symptoms were present during its administration. On an average the author used about 10 cc. of the agent in each case. This drug has proved a satisfactory anesthetizing agent in excisions of the eye. The drug should be given gradually and never "crowded" [J. H. G.]

3.—Copeman discusses headache in a thesis for the degree of Doctor of Medicine, Trinity College, Dublin. The seat of headache may be either in the scalp, the bones of the skull or its pericranium, or in the brain or its membranes. Headaches of intracranial origin he classifies as: (1) headache due to the lesions of the brain, meninges, or their blood vessels; (2) headache occurring in the course of acute fever; (3) headache due to congestion; (4) headache due to anemia; (5) headache due to nervous causes; (6) headache due to gastric substances; (7) headache of reflex or sympathetic origin; and, (8) sick headache or migraine. In the consideration of headache due to brain lesions and acute fever, he lays stress on the importance of directing attention to the disease of which the headache is a symptom. The clinical thermometer will serve to distinguish headache due to fever. The condition of the arteries and the age of the patient are valuable guides to diagnosis. Severe and persistent pain accompanied by nausea and vomiting are constant symptoms of the headache due to gross brain lesions. The result of the ophthalmoscopic examination and the fact that sooner or later paralysis of some of the cranial or some of the other nerves might develop, are valuable diagnostic signs. The following causes are mentioned for congestive headache. Valvular heart disease, hypertrophy of the left ventricle, chronic interstitial nephritis, plethora, emotional disturbances, irregular menstruations, the use of tight collars, and the abuse of corsets. He recommends aconite for the headache due to acute congestion, as a result of the hypertrophy of the heart, and digitalis and opium, in small doses, for the headache due to passive congestion. Cold applications to the head, saline purges, hot mustard foot baths, gentle exercise in the open air, and the proper regulations of the diet, are all valuable adjuncts in the treatment. The headache due to cerebral anemia is very common amongst all classes and in people of all ages. When this form of headache is due to a general anemia few drugs will give immediate relief to the patient. Improvement must follow more slowly. In chlorosis the administration of iron often produces rapid improvement. A glass of wine, preferably champagne, or the mere taking-up of the recumbent position often gives speedy relief. The headache of general debility and neurasthenia is known as nervous headache. The pain in this variety is not infrequently fixed in one small spot, but it may occur in any part of the cranium. In the treatment of this condition he recommends the bromides and camphor combined with absolute rest and quiet in a darkened room. The dilute mineral acids and preparations of iron, zinc, and arsenic are valuable drugs to strengthen the exhausted nervous system between the attacks. The following causes are mentioned for toxicemic headaches: Faulty digestion, imperfect action of the liver, acute al-

coholism, gout, rheumatism, malaria, lead poisoning, confinement in close stuffy, ill-ventilated rooms, and the inhalation of sewer gas. This form of headache is frequently frontal in character. When due to dyspepsia or bilious states, prompt relief follows the use of an emetic or brisk purgation. When the stomach is irritated bismuth and dilute hydrocyanic acid in an effervescent draught will relieve the patient. The following causes are given for reflex or sympathetic headache: Eye strain, dental caries, diseases of the throat and nasal passages and ovarian and sexual derangements. The treatment should be directed to the organ whence the irritation springs. Migraine or sick headache is now generally thought to be due either to a nervous disturbance of the nature of epilepsy, or to some other ill-defined condition of the cortex of the brain, while there are still others who hold that it is due to circulatory disturbances of the brain. The author is inclined to the view that this form of headache is due to a toxemia; the blood being saturated with toxic products from faulty digestion. In the treatment of this condition he recommends 5 grains of phenacetin and 2 grains of caffeine. 12 or 24 hours rest in bed is necessary before relief will be secured. [F. J. K.]

4.—Thomson read a paper before the Royal Medical and Chirurgical Society on "The Prognosis and Treatment of Ascites occurring in the course of Alcoholic Cirrhosis of the Liver." In this address he mentions the following interesting points: (1) Ascites in the course of alcoholic cirrhosis may be due either to the cirrhosis directly, or co-exist with that condition without being dependent upon the cirrhosis; (2) the prognosis of ascites directly due to cirrhosis is very unfavorable, while ascites occurring with cirrhosis but not directly dependent upon it, is not infrequently temporarily relieved and may even be cured; (3) the operation performed for the relief of ascites is only likely to be successful in those instances in which the peritoneal effusion is an associated condition and not directly due to it. From post-mortem observations he has classified the cases of ascites, which, during life, seem to be due to cirrhosis of the liver into 3 groups: (1) Those cases in which the ascites is found after death to be the result of an entirely different cause; (2) those cases in which the ascites is associated with cirrhosis but not dependent upon it; (3) ascites directly due to cirrhosis. In regard to the treatment of the later stages of cirrhosis of the liver, at the present time it is generally advised to tap the peritoneal effusion early, but the author contends that there is no good evidence to show that tapping has any favorable influence on those cases where the ascites is directly due to cirrhosis. In this article a table is appended giving the results of the radical operation for ascites which was introduced with a view of curing cirrhosis with ascites. In this table 11 operated cases are recorded. It is very difficult to draw conclusions from this inserted table. Thomson has clearly defined the limitations of this radical operation. He believes that the cases best suited for operation are those in which the ascites is not dependent upon the cirrhosis but exists as an associated condition. The presence of cirrhosis with ascites is not necessarily a contra-indication to operation. He also states there is good reason to believe that the operation should not be undertaken when active symptoms of cirrhosis have supervened; the ascites being directly dependent upon these symptoms, for the liver, in such cases, is in a condition incompatible with prolongation of life. Care should always be taken to decide whether the cirrhosis is latent. The only cases to be selected for operation are those which have been tapped several times. [F. J. K.]

5.—Buckley reports a rare case of purpura complicating diphtheria. The patient, a girl 10 years of age, first came under the observation of the author on October 8, 1900, when she was suffering from diphtheria. The disease had progressed 4 days. After an examination it was found that a membrane covered both tonsils and the uvula. The Klebs-Loeffler bacillus was isolated from the exudate. Antitoxin was administered, and on the 7th day the membrane separated. On the evening of the 6th day the patient had a spell of vomiting and recurrence of these seizures during the next 36 hours. Blood was found in the vomit and in one of the stools. On the 8th day a rash appeared on the elbow, which consisted of large deep purple papules. Numerous petechiae were seen on the buttocks. Fresh petechiae continued to appear on the face,

ears, elbows, and knees. The papular rash on the elbows became vesicular. These vesicles coalesced, forming large bullae which contained a dark, broken-down, bloody material. The elbows and the left hip were painful and very tender upon pressure, but no swelling showed itself. 40 days after the initial attack of vomiting the patient again vomited, but purpuric manifestations did not recur. The patient gradually made a good recovery. Buckley thinks this was an example of Henoch's purpura. [F. J. K.]

8.—S. F. Loughwood reports a number of interesting surgical cases treated in the general Hospital in Springfield. The first case is one of gun-shot wound of the head in which the patient was operated upon 10 days after the receipt of the injury because of motor aphasia, complete motor paralysis of the right arm and leg, and Jacksonian seizures. A large blood clot was removed from the motor area, resulting in complete recovery. At one time after the operation the patient had a number of Jacksonian seizures and became very violent. At this time chloroform was administered to induce sleep, which kept up eight hours after the chloroform was discontinued and terminated in perfect consciousness and quiet. The second case is also a gun-shot wound of the head in which there was complete paralysis, both motor and sensory, of the right arm. The patient was trephined 6 days after the injury. The bullet had only passed through the scalp and no fracture of the bone had taken place. When the dura was opened, however, considerable clot was removed. This patient made a good recovery and gained complete power in the arm. Another case reported is that of laminectomy for gun-shot wound. Death followed 2 days after the operation. Postmortem examination showed a wound at the apex of the lung and a wound passing through the spinal cord. The author concludes with two reports of amputation for gun-shot wounds and six cases of herniotomy. [J. G. G.]

9.—Dockrell writes on lichen from a histological point of view. He states that there are two varieties of pityriasis rubra pilaris, namely, the benign and the malignant. He points out that in pityriasis rubra pilaris the hair follicles are primarily involved, while in lichen the involvement of the hair follicles occurs later in the disease and is secondary; and finally that in this condition there is no tendency to the formation of a hyaline material. He defines lichen as a cutaneous disease of an inflammatory nature, being ushered in by an eruption of red conical papules. These papules vary in size from that of a pin's head to that of a split pea. They are either discrete, confluent, arranged in rings, or may become distinctly warty. Four stages of the disease are mentioned: (1) The acuminate stage; (2) the planus stage; (3) the hypertrophic stage; and (4) the verrucose stage. In this article he gives a report of 5 cases. [F. J. K.]

10.—Cautley discusses infantile scurvy. This author gives a report of 2 cases of scurvy which were due to a prolonged diet of sterilized milk and cream, and also reports 2 which were due to patent foods. He contends that the boiling of milk for infants is essential, except under certain circumstances, and that the longer milk is boiled and the higher the temperature to which it is subjected, the less will be its antiscorbutic value and nutritive principles. The slight tendency to scurvy which is induced by a prolonged diet of cooked milk may be remedied by the addition of barley-water and fruit juice. He finally emphasizes that it is highly illogical to argue that unboiled milk is a proper food for infants. [F. J. K.]

11.—Startin writes on the treatment of lupus and rodent ulcer with the X-Rays. He has had beneficial results with the X-Rays in lupus, rodent ulcer and certain other skin affections, and believes that the X-Rays are a valuable therapeutic agent. [F. J. K.]

MEDICAL RECORD.

August 3, 1901.

1. Hemolysis. S. J. MELTZER.
2. The Principles of Diagnosis of Lesions of the Spinal Cord. JOHN PUNTON.
3. Cerebral Abscess; Operation, Recovery. FLETCHER GARDNER.
4. Limitations of Surgical Work for the Insane. WILLIAM J. MAYO.
5. The Primary Treatment of Infected Wounds with Tincture of Iodine. CARL BECK.

1.—S. J. Meltzer presents a paper on **hemolysis**. Hemolysis in general means solution of the blood. The term, however, is now chiefly employed to designate the separation of the hemoglobin from the stromata of the red blood cells. The author is chiefly concerned in dealing with the biologic agents which bring about this end, **alien blood or alien serum**. The paper deals with a discussion of Ehrlich and Morgenroth's studies of hemolysis and Ehrlich's lateral-chain theory, and then the author details at length the results of his own experiments. He finds that normal and immunized serum lose their hemolytic power during their prolonged stay in the peritoneal cavity; that the loss is due to the complement of Ehrlich, or the alexin of Bordet and Buchner. The disappearance means absorption, and the disappearance of the complement in a much greater proportion than the balance of the fluid means elective absorption. However, as this elective absorption takes place also in a dead animal, it cannot be a vital phenomenon. It is probable that it has its explanation in some laws of osmosis and imbibition. A valuable bibliography is appended to the article. [T. L. C.]

2.—John Punton discusses the **principles of diagnosis of lesions of the spinal cord**. He arranges his conclusions as follows: (1) Determine whether the symptoms are due to a lesion affecting the spinal cord by reference to your knowledge of the function of its several parts, thus excluding those symptoms due purely to cerebral or peripheral lesions. (2) Next determine whether the symptoms are due to organic or to a functional lesion, or are simply produced by malingering. This can usually be done by careful methodical examination of all parts involved in the process, together with a study of the mode of onset of the symptoms, their duration, nature, and character, and other facts connected with the family, personal, and clinical history of the case. (3) Next determine the exact location of the lesions, whether it be extra-medullary, intra-medullary, systemic, or non-systemic in its invasion. This calls for ability to interpret correctly the nature and character of the symptoms produced by these lesions, taken into conjunction with their causes and the known liability of certain structures to such lesions. (4) When all these questions are correctly answered the diagnosis is to be made, and upon this the prognosis and treatment are based. [T. L. C.]

3.—Fletcher Gardner reports a case of **cerebral abscess with operation and recovery**. The patient was a young man of 21. He suffered all but two years of his life from ear trouble. The patient presented symptoms of pain in the mastoid and left eyebrow; had a temperature of 103° to 104°, and was rapidly becoming somnolent. The mastoid was opened and Schwartze-Stacke extenteration was performed, and the contents of the middle ear, the posterior wall of the meatus, and the whole of the mastoid except the tip were removed. The patient did well after the operation, but with a subsidence of fever a **paraphasia** new became noticeable and words were misused. The aphasia became more and more marked, and the general symptoms led the author to diagnose the presence of an abscess and decide upon an operation, which was performed. A large flap was turned back with the base down, and the trephine pin was placed one and a quarter inches behind and the same distance beyond the external auditory meatus. As soon as the button of bone was removed the brain bulged into the opening without pulsating. A groove director was passed through an opening in the dura in the direction of the ala of the opposite nostril and two ounces of extremely foul pus were discharged. The patient made a very gradual recovery. The author believes that in this case the lesion is to be explained by the fact that from the temporal lobe there proceeds to the frontal lobe a band of association fibres which are concerned with speech and any lesions of which cause paraphasia. A second band proceeds to the occipital lobe and a lesion of this causes alexia. Bacteriological examination of the pus taken 66 hours after operation showed a diplococcus, which was probably the prime cause of the trouble, and a rare, or new, bacillus, resembling that of tetanus, but the whole organism was much smaller. The bacillus forms a gas of most obnoxious odor. [T. L. C.]

4.—W. J. Mayo treats of the **limitations of surgical work for the insane** under three general heads. First, the surgical relief of physical ailments without regard to the mental condition; second, operations for the purpose of

relieving the mental condition of the patient; third, operations performed with the public welfare in view. In a considerable operative experience in traumatic epilepsies and periodical attacks of insanity from the same cause, this author has seen but two cases in which relief was marked and lasted long enough to deserve attention. In neither case was there a return of mental vigor, but there was amelioration, and both cases remained sufficiently well to warrant home treatment now for more than three years. The surgical cure of insanity, supposed to be due to a reflex irritation in a distant organ, needs but little discussion. The cases are usually reported early or the mental condition greatly exaggerated and the future process seldom justifies the early prospects. The most energetic work of this kind has been done by gynecologists. In an extensive experience the writer has seen few if any, cures brought about in this way. He believes that operations for the public welfare are of questionable propriety, and at the present time would not have legal sanction. [T. L. C.]

5.—Carl Beck describes the **primary treatment of infected wounds with tincture of iodine**. His method is to apply the tincture over the carefully dried wound-surface, and he has not been able to obtain cultures from areas so treated. A large number of cases have been treated with iodine in this manner, and no general disturbance has taken place, although in two cases iodine reaction was found in the urine three or four hours after the application. He calls attention to the fact that in cases in which iodine was used in this manner, it appears to permeate the tissues. [T. L. C.]

MEDICAL NEWS.

August 3, 1901. (Vol. LXIX, No. 5.)

1. Injuries of the Head in the New-born. ANDREW F. CURRIER.
2. The State of the Gastric Secretions in Chronic Rheumatism and Rheumatoid Arthritis. FRANK H. MURDOCK.
3. The Administration of Ethyl Chloride as a General Anesthetic, with Descriptions of a Mask for Its Use. MARTIN W. WARE.
4. The Therapeutic Uses of Tri-Chlorotertiary-Butyl-Alcohol. E. M. HOUGHTON.
5. Belladonna vs. Scopolia. REYNOLD WEBB WILCOX.
6. Ulcer of the Duodenum Considered from a Surgical Standpoint. D. S. FAIRCHILD.

1.—A. F. Currier found in sixty cases of various **head injuries in the new-born** the following: Indentations or depressions of the bone showed 2 of the right frontal; 16 of the left; 5 of the right parietal; 9 of the left; 1 of the right temporal; 1 of the occipital and left parietal. The depressions varied from one-half inch to 2 inches long, one-half inch to 1½ inches deep, and three-fourths to 1¼ inches wide. These generally disappear in a few weeks or months, but in some cases remain visible for years. In 17 cases there were fractures of one or more bones. In 1 case there were extensive dislocations of cranial and facial bones. In 5 cases the bones were fissured. In 5 cases the brain was injured. In 4 cases there were injuries during fetal life. There were 21 forceps deliveries, 3 high forceps and 3 versions. There were 12 normal deliveries, and 7 labors were prolonged, the period varying between fifteen hours and six days. There were 3 precipitate labors. There were 6 cases in which there was tumor of the scalp. In 23 cases there was hemorrhage of one variety or another. Of the abnormal presentations 2 were breech, 1 face, 1 face arms and cord, 2 occiput posterior. There were 5 cases in which there was coma and 6 of convulsions, 4 of paralysis, 1 of idiocy. In 24 cases there was deformity of the pelvis of one kind or another. Death occurred in 26 cases from various causes. In 3 cases the scalp was incised and the bone elevated, and in 1 there was trephining and elevation. [T. M. T.]

2.—F. H. Murdoch, after examining the **gastric contents** of six cases of **chronic rheumatism and rheumatoid arthritis**, found that the total acidity was generally increased, and that under treatment, not for the rheumatic condition, but for the gastric symptoms (distress in the stomach, bloating and belching), there was marked improvement in all the cases. He refers to various authorities as

follows. (1) Bouchard reports a case with swelling of the finger joints associated with dilatation of the stomach. (2) Ewald reports numerous cases in which the gastric symptoms were so marked that the pain in the joints was overlooked. Neither of these men make any mention of analysis of gastric contents; (3) Elmhorn examined the stomach contents of a patient suffering from rheumatism and found an absence or deficiency of gastric juice. The author advises, especially in chronic rheumatism, and rheumatoid arthritis a diet, not with a view of suiting the condition of the joints, but to suit the existing state of the gastric secretions. [T. M. T.]

3.—M. W. Ware gives the usefulness of **ethyl chloride**, and compares it with laughing gas as follows: In the administration of laughing gas we have rigidity, cyanosis and increased hemorrhage, while in ethyl chloride there is a small percentage of rigidity, but never cyanosis. Other advantages are its portability and the fact that it requires no expensive apparatus for its administration. As the drug is so fugacious it is not likely to give an overdose, and the danger of cumulative effect is practically *nil*. It is best administered to children and young adults, and is not advised to be used in robust individuals. The author places the failures of this anesthetic at five per cent., and gives the following reasons for them: (1) by a prolonged period of excitation, it being impossible owing to the fugacious character of ethyl chloride to produce the paralytic effect on the cortical centers; (2) although the patient is seemingly narcotic, any painful manipulation causes muscular rigidity as the expression of increased reflex excitability and this interferes with any finer manipulations. The author only recommends it in minor operations and as a preliminary to cut short the agonies of the early stages peculiar to chloroform and ether. [T. M. T.]

4.—R. W. Wilcox considers in a paper on **Belladonna vs. Scopolia** that scopolia rhizome as fluid-extract incorporated into a liniment is devoid of therapeutic action, and should not be substituted for belladonna root; on the contrary, belladonna root, under certain conditions, produced rise of temperature, pulse and respiration, flushing of the face, reddened mucosae, dry tongue, thirst, headache, drowsiness and dilatation of pupils. All these symptoms will be increased with the amount of the liniment used. It was thought that possibly the camphor interfered with the production of the symptoms in the use of scopolia liniment, but recent results show that it does not interfere with its action as far as the scopolia rhizome fluid extract is concerned. It certainly aided in the absorption of the active principle of belladonna root. [T. M. T.]

THE NEW YORK MEDICAL JOURNAL.

6. Specimen of Bone from Shot Fracture of Skull, Which Resisted Against the Brain for Forty-four Years. D. S. LAMB.

2.—E. M. Alger states that the diagnosis of cancer, particularly cutaneous cancer, is generally difficult. Warts and moles cannot be pronounced malignant with any certainty till considerable progress has been made, but such growths in males of the right age should be objects of suspicion. Sarcoma of the skin is rare, develops more rapidly, has secondary deposits sooner, affects younger patients as a rule, and has a comparatively slight tendency to ulceration. Tuberculosis of the skin commonly begins in childhood, the lesions are usually multiple, instead of single, the individual tubercle have more of a purplish color, and have none of the induration of cancer. In fact, they are distinctly soft. Syphilis is the cause of most errors in di-

agnosis, but aside from the history of the patient, the syphilis develops much faster; it is often indurated, but has none of the cartilaginous hardness of epithelioma. It ulcerates much sooner, showing a punched out edge, often an undermined one, and a more profuse discharge. Syphilis, too, has a marked tendency to heal on one side while advancing on the other in a serpiginous form. A week's observation and treatment will generally decide the question if doubt exists. As to prognosis in these conditions we will find in the individual lesions such slow growth that often the disease could hardly be considered a malignant one were it not for the possibility of metastasis. Primary cancer makes its reappearance after extirpation in one of three ways: A nodule appears in the scar, which is to be understood as indicating that a few cells have been overlooked, to renew the growth. Or the lymphatics nearest the growth enlarge and finally show secondary appearances very much like the original tumor. This taking up of cancer cells may occur very early, and may be far more extensive than can be determined by looking for simple glandular enlargement. A third cause for dissemination is involvement of the blood-vessels themselves in the growth, enabling large or small masses of cancer cells to break loose in the circulation and lodge in various organs. It is probable that very few of these cancer emboli survive the change, and that they only grow under favorable circumstances, otherwise we should have a much larger percentage of secondary growths in the lungs, which, from their location and the fineness of their capillaries, probably arrest most of these emboli. The same reasoning must explain the frequency of secondary growths in the liver and their rarity in the spleen. [T. M. T.]

3.—T. J. Harris, in **Treatment of the Eustachian Tube by Means of the Electric Bougie** draws the following conclusions: (1) The electro-bougie has a place in our aural therapy—though a less important one than was at first supposed; (2) It should be used after, and not before other methods of treatment; (3) It will be most liable to fail if any associated internal ear disease is present; (4) Its results are not always permanent—the stricture may reform—we may hope rather for a diminution than a disappearance of the tinnitus. Two cases totally relieved out of 25. Two cases partially relieved. (5) Its use is not without danger—and a proper knowledge of the anatomy of the parts and of the technique is essential; (6) It is a question whether the process is a true electrolytic one, or if in many instances the obstruction is a true fibrous stricture. [T. M. T.]

3. Practical Blood Examination. HENRY F. HEWES.
4. Rachitic Deformities of the Spine. J. S. STONE.
5. Measurements of Girls in Private Schools and of University Students. ARTHUR MACDONALD.

4.—J. S. Stone discusses **rachitic deformities of the spine**. The diagnosis of rachitic deformity is very easy. It does not occur as a rule except in the more marked grade of rickets. The usual deformity is a general kyphosis, extending from the lower cervical region downward, and most marked in the lumbar region. It generally occurs early in the course of the disease. This kyphosis is usually associated with round shoulders. Deformity of the spine is not usually proportionate to the deformity of the long bones, because it occurs usually to the greatest extent in those children who have never walked, but who have been propped up in chairs long before they are able to stand. Treatment consists in recumbency upon some firm, even surface. The recovery from rachitic deformity of the spine is usually complete if proper treatment be instituted early. [T. L. C.]

5.—Arthur MacDonald presents tables showing the results of the measurements of girls in private schools and of women University students. His observations are of

interest. He finds that girls in the private schools in Washington and Chatanouga are much more sensitive to pain than girls in public schools; that the girls in the private schools are less sensitive to heat and locality on the skin, but more sensitive to pain before puberty than after puberty. Considering University women, he has found those of poor nutrition, when compared with others, are inferior in weight and strength; in distance between the orbits, corners of eyes and from crown to chin, and in distance between zygomatic arches. In general the blondes are inferior physically to the brunettes. The first born (men and women) are more sensitive to pain than the second born, and the second born are less sensitive to pain than the later born. [T. L. C.]

1.—Happel submits a clinical study of an eruptive disease resembling variola but differing from it in so many ways that he questions the likelihood of this disease being a form of variola. The general characteristics of this disease are the same it differs only in degree. The period of incubation varies from 14 to 18 days. The symptoms from the 1st to the 3d day are the following: The onset is abrupt and is marked by chilly sensations; the temperature rises to from 102°F. to 105°F.; there may be vomiting but no prostration; delirium and convulsions are absent. On the 4th day there appears an eruption having the characteristics of acne. Rarely do shot-like papules appear. In women and children the eruption first appears on the face, while in men it shows itself about the forehead, cheeks and chin. The temperature at this time rapidly falls to the normal, and the patient appears well. On the fifth day the acne-like eruption becomes vesicular. The fluid in these vesicles at once assumes an opalescent appearance, the vesicles are unicellular and do not umbilicate. At the apices of the vesicles the serum exudes, dries, and turns brown; in some instances this gives the vesicles the appearance of being umbilicated. At this time they may rapidly dry up and recovery follows. The disease may then be said to have aborted. In other instances by the 6th, 7th, 8th, or 9th day the eruption may have spread over the entire body. Secondary fever does not occur. Scabs rapidly form and drop off, and by the 10th day the patient's skin may be entirely clear. When the eruption has involved the entire body the skin may not be clear until the 14th day. Occasionally papules form with the appearance of the acne eruption. These vary in size from a pin head to a split pea. They do not umbilicate and form unilocular cysts, and do not extend into the derma. With the appearance of the eruption convalescence begins. Fitting of the skin does not occur and vaccinated subjects are susceptible to the disease. The prognosis is favorable, the death rate being less than 2%. [F. J. K.]

2.—Beebe believes that there is ample evidence to show

that the epidemic of smallpox which prevailed throughout the United States and our new possessions during the past 2 years, differs from old fashioned smallpox, and he questions whether the term mild, modified, or light type of smallpox should be applied to this disease. There are, in fact, medical men who assert that this malady is not smallpox. [F. J. K.]

3.—Leroy discusses the sanitary features of smallpox. He emphasizes that this disease, above all others, should be stringently dealt with by the health authorities. In this article he points out the necessity of establishing immediate and strict isolation of the patient, the necessity of proper infection of all articles coming in contact with the sick, and the methods of vaccination. [F. J. K.]

4.—Spalding presents an article on the diagnosis of mild and irregular smallpox, as found in the recent outbreak in the United States. He refers to the statistics of an outbreak which occurred in Chicago. The first case was discovered on March 9, 1899, and in the 17 months that followed, 72 cases developed. Then there followed a short period without the appearance of a single case. On November 30, 1900 there came to Chicago an individual suffering from smallpox in the pustular stage. During the following 6 months 238 cases were reported. In both of these outbreaks typical cases were always present, but the greatest number of cases were deviations from the true type. Among the different varieties there occurred: One hemorrhagic case (fatal), 13 confluent cases (with 3 deaths), 24 semi-confluent cases (with 2 deaths), 54 severe discrete cases (with no deaths), 179 mild discrete cases (with no deaths), and 39 modified forms. In all of the modified cases there was evidence of more or less successful vaccination. In these 2 outbreaks the disease attacked almost exclusively those individuals not protected by vaccination. [F. J. K.]

5.—Leavitt gives the distinguishing characteristics between mild discrete smallpox and chickenpox, and summarizes these in a differential table. He states that smallpox may occur at any age. The period of incubation is 2 weeks; the onset is marked by headache, backache, fever, and general malaise, lasting from 3 to 4 days, and the eruption is a progressive one. It is more marked on the exposed parts, the extremities, and invariably occurs upon the palms. The eruption undergoes progressive changes from papules to vesicles, then to pustules, and finally crusts form. The vesicles are multilocular and the skin lesion involves the lower layers of the derma. The temperature is high until the eruption appears, when it falls and remains about normal for a week, and again rises except in the milder discrete forms. The eruption is quite uniform in size and frequently umbilicated. It lasts from 2 to 4 weeks, is painful to the touch, and may itch. Pitting occurs occasionally in the discrete form. There are no complications and vaccination is protective. The mortality is high in the hemorrhagic type and in the severe confluent. He states that the period of incubation of chickenpox is from 13 to 17 days and that this disease occurs only in childhood. The eruption is more marked on the unexposed portions of the body and is rarely seen on the palms of the hands or the soles of the feet. The eruption, which is very superficial, undergoes vesiculation and crusts form. The eruption lasts from 1 to 2 weeks and is not painful to the touch. There are no complications and the mortality is practically nil. [F. J. K.]

6.—Bracken calls attention to the fact that there occurred in Minnesota, during the past 2 years, 7211 cases of variola with 19 deaths. The clinical picture of the typical cases of variola that occurred in this epidemic correspond with that given for variola in medical text-books. He, however, clearly points out that the usual text-book description of variola will not be of service in making the diagnosis of all cases that occurred in this epidemic. From the statistics which the author has collected, he is convinced that vaccination absolutely protects against the form of smallpox in this outbreak. The remainder of the article is chiefly devoted to the consideration of vaccination. [F. J. K.]

7.—Baldy remarks that cancer of the neck of the womb is practically incurable. At the present time there is no cure for cancer short of surgery, and it is no abuse of language to state that this is surgery's disgrace. He objects to the statistics as presented by Johns Hopkins Hospital, which claims a cure of 20% or more of cancer

cases. Seventy-three cases of cancer of the cervix were operated upon there and 15 cases or somewhat over 20% are alive to-day. But 68 cases were rejected as non-operable, all of whom are dead to-day. Consequently only a little over 10% of the cases which have come to that institution are alive to-day. There is an additional possibility that one or two of the 10% were not cancer cases, since the microscope is not always a positive evidence for or against the disease. In addition to this 9 of these cases of reported cures have only passed from 10 months to 2½ years since their operation, and only 6 cases are alive from 1 to 3 years after the operation. It is impossible to say how many may die of the recurrence of the disease within the next 2½ years, hence less than 5% can be said to be cured. Baldy emphasizes the importance of the clinical manifestations even before the microscopic evidence as an aid to the early diagnosis of cancer of the womb. It is the clinical manifestations which incline the surgeon to a microscopical examination. The symptoms of early cancer are as plain as those of any other disease in its early stages, and the reason that it is not oftener detected is the fault of the observer. [W. A. N. D.]

8.—Hiram Woods reports three interesting cases of acute mastoiditis after the subsidence of tympanic inflammation in which this condition did not return. Generally it has been his experience that mastoid symptoms develop while the otorrhea continues or increases in amount. Occasionally the discharge lessens or ceases with the onset of mastoid inflammation. The first case reported is that of a girl eight years of age who made a satisfactory recovery after an attack of acute middle ear disease. Nine days after the otorrhea had ceased she developed an inflammation of the mastoid which required operation. A satisfactory recovery followed the operation without any return of tympanic inflammation. One symptom which was present during the first attack remained until after the operation; this was torticollis. Case No. 2 was a boy, 14 years of age, who 12 days after the disappearance of all symptoms of an acute otorrhea developed an acute mastoiditis. The mastoid cells in this case were filled with pus and granulations. The extent of suppuration, however, was small as in the first case. The wound was closed in this case after operation but opened spontaneously later and healed by granulation in three weeks. The third case was that of a boy 14 years of age who three days after the cessation of an otorrhea developed pain over the mastoid and torticollis. The membrane was normal, presenting a healed perforation, except for a slight hyperemia of the malleus plexus. The patient suffered considerably from earache and an incision in the membrane was made for its relief. The torticollis disappeared, the temperature came down, and the patient was sent home. One week after the incision of the membrane the patient's temperature rose and he suffered from headache. No tenderness was present at this time over the mastoid and there was no otorrhea. The patient's pulse became slow, however, with an occasional intermission. The headache was confined to the left side and was most severe on the supra-orbital region. About this time the left pupil became dilated. The patient grew weaker and nothing definite developed. The transient symptoms of mastoiditis and the neck rigidity, however, caused the author to decide upon an exploratory mastoid operation. A little pus was found in the tip of the mastoid and when the antrum was opened there was a gush of clear fluid. The patient made a satisfactory recovery. The headache disappeared and the day after operation the pupils were equal. The author does not think well of the application of cold in acute mastoiditis but rather inclines to the opinion that its use only masks the symptoms.

[J. H. G.]

9.—Amberg gives a brief description of his modification of Lister's apparatus for the application of hot and cold water to the ear. Two illustrations of this apparatus are inserted in this article. [F. J. K.]

10.—J. Henry Barbat after showing the great advancement made recently in the diagnosis and treatment of renal and ureteral conditions refers to what the X ray, the Harris segregator, and Kelly's method of ureteral catheterization, have done in aiding the diagnosis of difficult and doubtful renal conditions. He reports some most interesting experiments upon dogs in which he has endeavored to use a portion of the small intestine to bridge over the gap between the cut ends of the ureter.

A portion of the ileum was usually chosen, a piece of which was excised without disturbing its mesenteric attachment. The calibre of the remaining intestine was re-established with a Murphy button. The portion excised was thoroughly irrigated with a 1:1000 formalin solution. The proximal end of the ureter was then firmly fixed in one end of the piece of intestine and the other end of the intestine inserted into the bladder. Three such operations were done. In two the result was perfect; the third dog died five weeks after operation of an ascending infection due, the author thinks, to his not having thoroughly cleansed the portion of bowel used. One dog was allowed to go three months and another six months before removing the specimens. In one case both ureters were implanted into a loop of bowel which was attached to the bladder by a lateral anastomosis. The dog died, however, from an overdose of strychnine. In one dog a complete removal of the bladder was made and a portion of the bowel substituted for it. The dog died with an enormously distended new bladder and some slight leakage at the urethral attachment. It is thought this death might have been prevented had catheterization been possible. [J. H. G.]

11.—J. M. Brown reports several cases of papilloma of the larynx which have been cured or greatly improved by the application of the *Thuja occidentalis*. [J. H. G.]

12.—This is an abstract of an address of "Scientific Research," delivered by the President of the British Medical Association at the 69th annual meeting. [F. J. K.]

VRATCH.

April 28, 1901. (Vol. XII, No. 17).

1. Changes in the Composition of the Blood of Animals in Intestinal Auto-intoxication. I. A. KRASNOFF.
2. On Sporadic Elephantiasis. L. V. ORLOFF.
3. Chaffkin's Lymph and Other Substances Elaborated by the Human Organism, Producing Immunity Against the Plague. A. F. VIGOURA.
4. The Treatment by Koumiss and Some of the Koumiss Settlements of the Government of Oufin. P. V. TSEZAREVSKI.
5. On the Question of Reforming the Suvoroff School at the Kalinkin City Hospital at St. Petersburg. P. E. OBOZNEENKO.

1.—Krasnoff has under taken the study of the quantitative changes produced in the blood by auto-intoxication. For this purpose he produced an artificial cleatrical narrowing of the lumen of the large intestines of dogs, causing constipation and determined before and after the operation the number of red and white blood corpuscles, the amount of hemoglobin, the specific gravity and the amount of iron. The present paper is a preliminary report which contains the following conclusions: (1) The number of red blood cells is diminished, maximum 72.5%, minimum 15.6%. (2) The white blood cells are either diminished or increased; Maximum diminution 80%, minimum 10%; maximum increase 60%, minimum 10%. (3) The amount of hemoglobin is uniformly decreased. (4) The specific gravity is lowered but not always in proportion to the decrease in the number of the red blood cells. (5) The amount of iron is diminished. [A. R.]

2.—Orloff reports 4 cases of sporadic elephantiasis. Case 1. Elephantiasis of the scrotum and left leg. The patient, a man of 28, a mine worker, suffered from repeated inflammations of the scrotum for a period of 13 years. Each attack was accompanied by redness and swelling of the scrotum lasting a few days and followed each time by a greater enlargement of the scrotum. On the fifth year after the onset the glands of the groin began to suppurate and a purulent discharge appeared from a fistula formed in the skin of the scrotum. 3 years later the left leg became the seat of frequent attacks of inflammation followed by enlargement of the extremity. At the time of admission the scrotum was considerably enlarged, the lower border reaching almost to the knees. Internal medication having proved useless, the larger portion of the scrotum was removed, leaving enough to enclose the testicles, which were normal. After a protracted convalescence, the patient recovered. Case 2. Elephantiasis of the scrotum and prepuce. This case was of 15 years standing. The swelling was preceded by attacks of inflammation. Removal of the scrotum and a plastic operation on the penis restored the parts to their normal size. Case 3. Elephant-

trias of the penis and the right lower extremity in a man 21 years old. The case was of 9 years standing and there was a history of suppuration of the glands of the axillae and the groins and an attack of erysipelas on the right leg. For the last 3 years erysipelatous inflammations of the leg occurred 19 to 12 times, each attack being accompanied by an elevation of temperature. There were also syphilitic dermatitis which made their appearance when the patient was 11. Antisyphilitic treatment having proved of no avail, a plastic operation was performed on the penis. The affected skin was removed and new skin from adjoining parts grafted on. The results were quite satisfactory. Case 1. Elephantiasis of the abdomen. A woman, 59 years old, disposed to obesity, had 3 attacks of erysipelas of the abdomen within 2 years. After the first attack the abdomen began to enlarge until it assumed the shape of an apron hanging down 10 cm. below the knees. Locomotion was almost impossible, and an extra stool was required to support the mass when sitting. Injections of calomel had no effect, and excision of the hypertrophied skin was performed. The removed mass weighed about 56 pounds. Recovery was delayed by ulceration of the wound and slow granulations. Considering the etiology of elephantiasis, the author reviews both forms of the affection, the endemic and sporadic. The former occurs mostly in hot climates and is caused by the *filaria sanguinis hominis*, with the mosquito as the intermediary host. The latter is caused by venous stasis and interference with the circulation of the lymph. Erysipelas, lymphangitis, phlebitis, or any condition producing circulatory disturbances, must be the direct factor in the causation of elephantiasis. As to treatment, various remedies, such as mercury, iodide of potash, quinine, etc., have been recommended and applied but without any effect in the majority of cases. An operation is often the only means of accomplishing a cure. Various operative procedures, as well as the conditions in which they are indicated, are discussed and illustrative cases cited from the literature. [A. R.]

3.—Will be abstracted when concluded.

4.—Tsezarevski describes in detail a number of results for the koumiss cure, a treatment very popular in Russia, employed with considerable success in various forms of exhaustion. The koumiss is made from mares' milk which is allowed to ferment. The beneficial results achieved are due as much to the climate of the steppes as to the beverage. [A. R.]

2. Contribution to the Home Treatment of Tuberculosis by Hydrotherapy. H. MEFFERT.
3. The Serum Diagnosis of Tuberculosis.

E. ROMBERG.

4. On Occupation Poisonings (Methemoglobin) and their Treatment by Oxygen Inhalation. H. BRAT.

H. BRAT.

2.—Meffert recommends that the patient be placed on a bed which is first covered with a large woolen blanket, over which one places two shorter blankets of such size that one will serve to envelop the trunk, the other the legs, separately. Over these is placed a sheet. The patient is wrapped in these coverings in a "dry pack" until thoroughly warm. His trunk is then uncovered, he sits erect and is sponged a few moments, the trunk then covered without drying and the same procedure carried out with the legs. He then lies in the damp pack until dry and warm. Then he steps into a chamber bath containing luke warm water and is given a shower bath from a sprinkling pot for 30 seconds. He is then thoroughly dried and clothed. Meffert recommends this treatment both in hospital practice and in private where it can be used for the poor patients as well as the rich. [D. L. E.]

3.—Romberg presents a new and much more satisfactory method of carrying out the serum diagnosis of tuberculosis which was first attempted by Arloing and Courmont. The great difficulty has always consisted in getting homogeneous cultures; these can be secured only after long effort and the attempt may and often does end in failure. Behring found that emulsions of dead tubercle bacilli are agglutinated quite as well as the living bacilli in homogeneous culture, and communicated this observa-

tion to Romberg. The latter has used it clinically. The blood serum is freed completely by centrifuge, from red cells 0.5 c. c. mixed with the emulsion in equal parts and then 0.2 c. c. of serum is mixed with 5, with 10, 15, 20 and 30 times each of the emulsion of bacilli, using small test tubes. The tubes are placed in the thermostat kept at the same temperature. The reaction must take place within 40 to 44 hours if the result is to be considered positive. Naked eye observation is best. The cloudy mixture should become perfectly clear if the result is wholly positive and a precipitate should settle at the bottom of the tube. Ninety-five human beings were tested, many of them repeatedly. The blood of six new-born children showed absolutely no reaction, even though the mothers of all showed advanced tuberculosis. Of 39 adults who showed no suspicion of tuberculosis, 22 gave a reaction. These results Romberg attributes very positively to the existence of latent tuberculosis. One point that spoke for the truth of this belief was that the positive reactions were found chiefly in young persons, the figures for reactions corresponding very closely as to the age of the subjects, with Macgill's figures for latent tuberculosis. Romberg thinks it possible that a negative result of this test in a person who shows signs of tuberculosis may have to mean that he has old, inactive and not "latent" tuberculosis. Of 30 persons with early tuberculosis, 26 (86.7%, gave no reaction. Of 11 with marked disease 8 (72.7%) gave the reaction. Of 2 very advanced cases one gave the reaction. Of the total 8 negative cases 6 were very severe, rapidly advancing cases such as at times will not react to tuberculin, and will not give Arloing and Courmont's reaction. Romberg states that the only conclusion that one can reach is that a positive reaction probably means the presence of active tuberculosis, while a negative reaction probably means either that tuberculosis does not exist in the body or that, if it does exist, it is old and healed, but even this conclusion is not yet justified and further investigation is necessary. Only in the general sense of showing that tuberculosis in some form is present could the reaction be of any real diagnostic value. It could not point out a more definite local diagnosis.

[D. L. E.]

4.—To be concluded.

May 16, 1901.

1. Concerning the Morphology of Bacteria and its Relation to their Virulence. G. ASCOLI.
2. Occult Gastric Hemorrhages. I. BOAS.
3. A Simple Gas-Volumetric Method of Estimating Sugar in the Urine. E. RUEGLER.
4. The Magnet-Operation Room. J. HIRSCHBERG.
5. On Occupation-Poisonings (Methemoglobin) and their Treatment by Oxygen-Inhalations. H. BRAT.

1.—Ascoli refers to the work of Marx and Writhe and others concerning the relation of the Ernst bodies in bacteria to their virulence. He disagrees with those who think that there is any direct relation between these bodies and the virulence of the bacteria. They are not spores and do not form spores, nor are they evidences of a possible karyokinesis. They are closely related to the development of the bacteria, and may be degenerative products, or evidences of advancing development; which of these is not known. At any rate Ascoli's experience leads him to believe that they have absolutely no constant relation to the virulence of the bacteria. He also thinks that there has never been any real demonstration of the presence of nuclei in bacteria. [D. L. E.]

2.—Boas has undertaken a series of investigations for blood in gastric contents when its presence was not evident to the naked eye. He used the guaiac test, which he considers best. He recommends shaking the etherguaiac terpenine solution with water and chloroform and allowing the mixture to stand a long time. Examination of the stomach contents removed by the tube, not of vomit, should be undertaken. The results of the examination of 83 cases lead him to the statements that even when blood cannot be suspected from the naked eye examination, the guaiac test is often positive in gastric ulcer or pyloric stenosis from ulcer and in other cases in which there is marked stagnation of stomach contents. Blood was repeatedly found in one case of duodenal stenosis. The most striking result was the constant presence of blood in twenty cases in carcinoma. It was always absent in neuroses, gastritis

and benign stenosis. He believes that in doubtful cases the presence of small amounts of blood would be important evidence of ulcer as against neurosis, and on the other hand of cancer as against gastritis or benign stenosis. He thinks this "occult hemorrhage" one of the main causes of the early cancer cachexia, and believes that its discovery and proper treatment will lead to important results in the management of cases of carcinoma and ulcer.

[D. L. E.]

3. The method depends upon the use of a special apparatus, the details of which can be understood only by examining the original paper. The principle of the method is, first, reduction of copper to oxide by the sugar of the urine, then heating this copper oxide with hydrozin sulphate in the presence of a base; the copper is reduced to the metal and nitrogen in quantities proportionate to the amount of copper oxide present, is set free. The amount of gas is determined and the amount of sugar is then calculated from a table. [D. L. E.]

5.—Irat has had excellent results from the treatment of methemoglobinemia occurring in those working in aniline dye establishments, etc., by inhalations of oxygen. He based this treatment partly upon the experience of others and partly upon the fact that he noted marked levo-rotation in the urine of these subjects, and that this was associated with the presence of glycuronic acid, and was probably due to its presence. This indicated to him that oxidation processes were reduced as he follows the teaching of Meyer concerning glycuronic acid (abstracted from *Deutsch. Med. Woch.*, April 29th and 27th). He admits that previous work seems to have shown that inhalation of oxygen does not cause any increase in oxidative processes in the body and actually passing oxygen through methemoglobin solutions had no effect. Addition of an alkali to the latter solutions, however, increased their power of absorbing oxygen, and he believes that in the alkaline blood, and more especially if the blood alkalinity be heightened, oxygen may alter methemoglobin so that it at least approaches hemoglobin in its character. One of the best means of increasing the alkalinity he considers to be blood-letting. He found in animals that blood greatly increased the alkalinity. He also thinks that oxygen inhalations may do good by completely saturating all the healthy hemoglobin present. [D. L. E.]

CENTRALBLATT FUER CHIRURGIE.

June 29, 1901. (28 Jahrgang, No. 26).

1. An Attempt to Simplify the Treatment of Pseudarthrosis. F. COLLEY.
2. The Technique of a New Operation for Phimosis. HERMAN SCHLOFFER.

1.—Colley reports a case of united fracture of both bones of the forearm, in a strong man of 23, with delirium tremens. There was absolutely no callus formed. Fearing to perform a large operation upon such a restless patient, Colley injected 10 c.c. of a mixture of pulverized bone ash (of the femur of a steer) in distilled water and gum arabic, every four weeks. After the sixth injection, both radius and ulna showed permanent consolidation. [M. O.]

2.—Schoffer has devised a new operation for phimosis, which can only be performed upon a normal, undiseased foreskin. Two incisions are made in the outer layer of the prepuce from one point at its edge, at a right angle to each other, as far as the corona glands. As the foreskin is retracted, a denuded surface, oblong in shape, is seen, which is sutured to form a transverse line. Then the wide prepuce can be replaced over the glans as a protection. The technique is described and illustrated by diagrams. Phimosis cannot recur. This operation is only possible when the two layers of the prepuce are freely movable. [M. O.]

DEUTSCHE ARCHIVE FUER CHIRURGIE.

18. The History of Circular Pylorectomy. ALFRED STIEDA.
19. Exclusion of the Intestine with Entero-anastomosis. FRIEDRICH ROSKOSCHNY.
20. Perimetry of the Joints. C. HUEBSCHER.
21. Surgery in the Bible and Talmud. J. PREUSS.
22. The Surgical Significance of Morel-Lavallée's Traumatic Separation of the Skin. BERNHARD MOELLERS.

23. Splenectomy for Primary Splenomegaly. M. L. HARRIS and MAXIMILIAN HERZOG.

21. Winkelmann's Hydrocele Operation. OHL.

25. Casualistic Communications. GELPKE.

26. An Apparatus for Closing the Sacral Anus Formed after Resection of the Rectus. ERWIN PAYR.

18.—Stieda has written an able review of the work done and the publications which have appeared upon resection of the pylorus, to show that Rydygier's claim of having originated the method commonly called Billroth's method of performing circular pylorectomy, is not borne out by facts. The first operation of this kind was done by Péan in 1879, the second, by Rydygier, in 1880. Both patients died. Billroth performed the first successful circular pylorectomy in 1881, and described the technique in full. Both Merrem and Gussenbauer had made experiments upon animals at this time. From this very truthful and convincing paper no doubt remains that the first method of resecting the pylorus was Péan's; the second, not Rydygier's, but Billroth's. [M. O.]

19.—Up to 1885 there are but 47 cases of simple entero-anastomosis reported. These were performed for clerical stenosis, from chronic inflammation, tuberculosis, and malignant tumors; for fecal fistulae; invagination, acute or chronic; and gangrenous herniae. Later, when the operation was performed, the intestine affected was left in place entirely cut off, other connections being made so that the affected intestine was excluded from the track of the fecal material. After a full review of the history of these operations, with quotations from the literature, Roskoschny reports 18 cases of partial exclusion of the intestine, and 16 cases of total exclusion. All the case-histories are given in detail, with diagrams to show the path of the intestinal contents before and after entero-anastomosis. 7 out of 34 cases died from the operation, four of pneumonia, three of peritonitis. In only one of these was total exclusion performed. 17 of the cases were male, 17 female. In 24 cases the cecum was affected. Total exclusion of the fistula cured 5 cases of fecal fistula. Of the 16 total operations, the ileum was excluded 16 times, the cecum 14, the ascending colon 16, the transverse colon 2, and the splenic flexure once. Of the 18 partial operations the ileum and ascending colon were excluded 7 times, and the ileum and transverse colon 6 times. Lateral apposition with sutures was used 24 times, Murphy buttons 8, and lateral implantation of the ileum in the colon twice. Silk was employed as the suture material. Of the 18 cases of partial exclusion of the intestine, three are still alive, two perfectly well and at work, the other at home. Of 5 other cases nothing is now known. Of the 16 cases of total exclusion of the intestine, 7 are yet alive, 1 perfectly well. Of four others nothing is known. A table of the 34 cases follows. [M. O.]

20.—Huebscher describes the use of the perimeter to measure the movements of the joints, giving the field of motion diagrammatically. Each joint is discussed separately, with drawings to show the different uses of the perimeter. After a most detailed description, he concludes that the field of the excursion of motion in the different joints of the human body is easily measured by the perimeter; that in the treatment and prognosis of accidents, the range of motion left will indicate the amount of damage done; that the action of the faradic current upon the normal muscles will give a normal physiological field of motion; that in paralysis, perimetry quickly aids in the discovery of the muscles affected, and so assists therapy; and that flat-foot will be revealed by perimetry even in a latent stage, by the insufficiency of the supinator muscles. [M. O.]

21.—Preuss has written a detailed and entertaining account of surgery as it is mentioned in the bible and the talmud. He quotes many interesting passages.

22.—Morel-Lavallée called the condition of the skin when it is separated by a force attacking it at a tangent, the space between skin and fascia filling up with serum, traumatic separation of the skin and its underlying layers. Moellers reviews the literature of this separation, in injuries occurring both in time of peace and war. The main cause of this accident is a rolling wheel. The direction and the intensity of the force will determine the depth of the lesion. The upper part of the lower extremity is most frequently affected. The separation may be deep or superficial, generally the latter. The fluid which accumulates under the skin varies in amount. It is generally little in

comparison with the size of the space between the skin and the fascia. It is serous fluid of low specific gravity. While fluctuation is never felt, a certain undulation exists. The skin is normal in color, but can be shoved about abnormally. It is not sensitive, but shows a tendency to gangrene. Diagnosis is generally easy, from the undulation, the regularly increasing effusion of serum, and the relief afforded by a change of position. The condition occurs frequently. The prognosis is not unfavorable. The fluid should be evacuated by an incision, and the cavity irrigated. The accident will heal in about two weeks. The condition is most common in war, due to the action of the bullets. It is more often deep than superficial. Finally Moellers reports a rare case in which the retina showed this condition. [M. O.]

23.—Harris and Herzog report two cases of successful splenectomy for primary splenomegaly, or splenic anemia, which were performed in Chicago. In the first case a young girl of 22, the disease ran a chronic course, with leukopenia; in the second, a man of 47, it was acute, with marked leukocytosis. The literature of the subject is given. In the first case hematemesis occurred. Both cases recovered after operation. The pathological and histological appearances found follow in detail. There was a marked increase of the lymph-endothelium; and the remains of destroyed blood corpuscles in great numbers were found in the dilated splenic pulp. The treatment of the 19 reported cases of splenomegaly is detailed in tabulated form. 14 cases recovered with splenectomy. The technique of the operation is meagerly given, and a number of drawings show the character of the enlarged spleens. [M. O.]

24.—Ohl reports 19 cases of hydrocele treated by Winkelman's operation. Local anesthesia was employed in all but one case, in which a hernia was also operated by Bassini's method. The results were excellent in every case. [M. O.]

25.—Gelpke reports some of his interesting successful cases: A man of 22 with severe traumatic tetanus, cured by intracranial and intravenous injections of anti-tetanic serum, 140 g. in all; a resection of the upper jaw in a boy of 12 for adenoma of the base of the skull; brain abscess in a child of 6, with paralysis of the right arm and epilepsy, cured by trephining; a 6 year old girl with fracture of the skull, in the temporal region, cured by puncturing the dura; a tuberculous kidney from a woman of 41; a resection of the stomach in a woman of 67; and a case of pseudo-pernicious anemia due to the bothriocephalus latus. [M. O.]

26.—Payr describes and gives photographs of an apparatus for keeping the sacral anus formed after resection of the rectum closed. It is like a truss, supported over the shoulder and about the waist. [M. O.]

BERLINER KLINISCHE WOCHENSCHRIFT.

June 10, 1901. (No. 23.)

1. The Dietetic Treatment of Epilepsy. R. BALINT.
2. A Case of Hemorrhage From the Internal Carotid Artery Following a Cholesteatoma. HEINE.
3. Is Cancer Curable? A. ADAMKIEWICZ.
4. The Symptomatology and Therapy of Appendicitis. KAREWSKI.
5. Concerning a New Electrical Therapeutic Procedure. P. RODARI.

1.—R. Balint recommends for the treatment of epilepsy the removal of sodium chloride from the diet and replacing it by a bromine salt. Even the bread should be specially prepared by baking it with a bromide instead of table salt. The author reports favorable results in the 28 cases of epilepsy he treated and states that there were no symptoms of bromism. His conclusions are as follows. (1) In every case of epilepsy a diet deprived of sodium chloride is applicable and should be tried. (2) The treatment is most successfully carried out in an institution. (3) Until a thorough knowledge of the character of the disease is ascertained, a rigid diet deprived of sodium chloride should be instituted. (4) In addition to this form of diet, small doses of bromides should be administered. (5) The introduction of bromides into the nutriment and especially into the bread as a substitute for the sodium chloride is to be recommended, as it is an agreeable way of administering the drug. The favorable result of this treatment is to be attributed to the ascending dosage and the consequent sedative action of the bromine, and is therefore also to be

employed in other nervous diseases in which large doses of bromides are indicated. [M. R. D.]

2. Heine reports a case of hemorrhage from the carotid followed by a cholesteatoma, occurring in a woman 56 years of age who had been suffering since three years of age from middle ear disease. A mastoid operation was performed and another one six months later. Hemorrhage then repeatedly occurred after the operation but was checked by packing. About a month after the last operation another grave hemorrhage occurred and two days thereafter the patient got out of bed during the absence of the nurse upon which a severe hemorrhage immediately took place. The patient was at once placed under an anesthetic, the bleeding focus exposed and the hemorrhage checked by packing. The patient died four days later from edema of the lungs. Postmortem examination showed an erosion of the internal carotid at its angle in the carotid canal. The dark color of the blood which was observed during the hemorrhages led the author to suspect that the hemorrhage was of a venous character, as did also the absence of pulsation. The latter phenomenon was accounted for by the fact that the internal carotid was found markedly thickened for some distance each side of the bleeding focus with a consequent lessening of its lumen. [M. R. D.]

3.—A. Adamkiewicz reports a case of a woman, 58 years of age with a pelvic carcinoma involving the uterus, vagina and parametrium and whose condition had been declared as inoperable by Albert of Vienna. The woman markedly improved under injections of "cancerin," the rectal and vaginal symptoms having disappeared. The author even states that the problem of the therapy of cancer has been solved. [M. R. D.]

4.—Will be abstracted when concluded.

MUENCHENER MEDICINISCHE WOCHENSCHRIFT.

6. Additional Notes upon My Work About the Influence of Carbon upon the Tubercle Bacillus. J. PAPASOTIRIU.
7. The Vaporization of the Uterus. S. LACHMANN.
8. Causes and Treatment of Menstrual Colic, (Dysmenorrhea). THEILHABER.

1.—(See editorial.)

2.—Stark discusses the Moeller-Barlow disease in children. He admits that the American idea that it is merely a form of infantile scurvy produced by improper feeding, is probably correct. His own experience has failed to convince him that it has any particular relation to rachitis or to hereditary syphilis. The diagnosis is often difficult. The most important symptom, the hemorrhagic swelling of the eye-lids, is often absent. The causes are numerous. It may even occur in children fed upon breast milk, if this is imperfect, but the great majority of cases occur in children who have been fed on sterilized milk, Mellin's Food, malted milk, and other proprietary preparations. In Germany almost all the forms of artificial nutrition may give rise to the disease. It is interesting to note that there seems to be a geographical distribution. In some districts such as Hamburg, it is exceedingly common, and in others, such as Munich, it is exceedingly rare. The proper diet is very difficult to determine. In many cases the children do best upon ordinary raw milk, but children differ so much in their ability to take certain diets that it is very difficult to decide in advance, which will, and which will not produce Barlow's disease. Starck has observed one family in which 11 children were raised successfully upon undiluted raw cow's milk. [J. S.]

3.—Kuhn reports the following extraordinary case, A man of 18 had a severe attack of typhoid fever, in the course of which there was albuminuria and excessive meteorism. During convalescence there was thrombosis of the right femoral vein, associated with rise of temperature. Thirty days after the cessation of the fever the patient developed severe pain in the left lumbar region, followed by pains in the sacrum, complete prostration, and high temperature. Any attempt to move the body caused intense agony. The pains gradually disappeared the fever diminished, but at the same time the lower lumbar vertebra became slightly prominent and tender upon pressure. This condition persisted for some time, until a distinct kyphosis was produced, although when the patient was able to leave the hospital it had disappeared to a considerable extent. The case resembles one reported by Quilcke, of typhoid spondylitis. This usually comes on some times after defervescence, and may be associated with the presence of typhoid bacilli in the medulla of the bone.

[J. S.]

4.—Hämig reports the case of a man 59 years of age upon whom the removal of the right kidney had been performed on account of carcinoma that involved the vessels and the ureter. Everything went smoothly until the 6th day, when the patient, who in the meantime had had no evacuation of the bowels, complained of tympanites. The following day there was collapse, and the condition of the patient became so much worse that it was impossible to think of operation. All the signs of acute intestinal obstruction were present. As the outcome seemed necessarily fatal it was decided as a last resort to give him an injection of atropine, and 1-20 gr. was accordingly given. The physiological results were very pronounced. There was dilatation of the pupils, active delirium and small filiform pulse. The following day the patient was better but it was necessary to give him a subcutaneous injection of normal serum. The pupils had become normal in size, the bladder was evacuated of 1300 ccm. by catheter, and there was some feculent vomiting. The same evening an injection of oil produced an abundant evacuation of the bowels, and the patient rapidly recovered. The cause of the obstruction could not be determined. It is not likely that peritonitis existed, there were no signs of hernia, it is possible, however, that thrombosis had occurred in the mesenteric artery. [J. S.]

5.—Frank opposes the suggestion of Scévos-Zérvos, that the Greeks were familiar with the disinfectant properties of alcohol. He quotes extensively from the literature to show that it was not until the 12th century that distillation was so well known as to enable us to obtain concentrated alcoholic preparations, the only ones of course that are available for disinfectant purposes. He gives then some quotations from recent literature to show that alcohol has become more and more popular as a disinfectant.

[J. S.]

6.—Papanotriu corrects his former statement regarding Frankel's use of charcoal in wounds. He now admits that Frankel believed the action was due merely to the stimulation of the hyperplasia of the connective tissue.

[J. S.]

7.—Lauman continues his article upon the vaporization of the uterus. The effect is usually limited to the most superficial area, although in some cases it may cause complete necrosis of the mucous membranes. The general indication for its use is climacteric and pre-climacteric uterine hemorrhage. It is of very doubtful value in endometritis, partly because we are not sufficiently acquainted with the etiology of this disease. He mentions a case of his own in which it was employed in a woman of 29 for uterine hemorrhage. The hemorrhage was not cured, and it was necessary to extirpate the uterus, when there was found cystic distention of the glands of the cervix causing a formation of a tumor mass in the wall of the uterus. In 14 cases of this condition only 6 were really improved. Two have withdrawn from observation. He

has not treated puerperal diseases, and considers hemophilia as a very rare indication indeed. He is very much opposed to the employment of vaporization for the treatment of prevention of carcinoma, and condemns particularly Scheehold's method of treating uterine carcinoma after this method in preference to an immediate radical operation. Among the complications are elevation of temperature, the development of infection, of which he reports 3 cases, and the production of obliteration of the uterine cavity, which may occur after moderate applications of the vapor. In fact, in some cases total extirpation has been required. When the operation is performed it is necessary to keep the patients in bed for a considerable time, and it has been Lachmann's custom to employ vaginal lavage with lysol 3 times a day. In conclusion he considers that vaporization is of value in climacteric and pre-climacteric hemorrhage, but it should be very cautiously used in other conditions. [J. S.]

8.—Theilhaber, in continuation of his discussion of the causes of dysmenorrhoea, calls attention to the great probability that the condition is almost invariably due to spasm of the internal os. This may be due to nervous conditions. Regarding the treatment, of course the hygienic one is most important. The patient should be exercised, given cure for the nervous system, and any constipation should be relieved. It is possible that the application of cocaine to the nose may be of advantage. As it has been observed for such a long time that parturition frequently cures the condition permanently, Theilhaber has devised an operation which he believes produces the same result in the same manner, that is to say, an incision of the internal sphincter. It is his custom to remove a small wedge-shaped portion from the uterine wall, and from the inner end of the cervix. He controls bleeding by tampons which are removed on the 3d day. Usually narcosis is not necessary. In 14 patients upon whom the operation was performed in this manner, all have been permanently recovered, and in some the result has lasted for more than a year. [J. S.]

WIENER KLINISCHE WOCHENSCHRIFT.

May 3, 1901. (XIV Jahrgang, No. 22).

1. Iodoform-Solder. NIKOLAUS HACKMANN.
2. Bier's Spinal Anesthesia. RUDOLF TRZEBICKY.
3. A Case of Subcutaneous Rupture of the Patellar Ligament. F. PENDEL.

1.—After a full review of the surgery of bony caries, necrosis, etc., Hackmann describes an iodoform-solder, an idea of von Mosetig's, especially of use in treating those morbid processes in bone which cause the formation of cavities. This solder is composed of spermaceti 40; old sesam 20; and iodoform 30 or 60. von Mosetig employs it in diseases of the bones and joints. Hackmann details an apparatus made by him for liquefying the iodoform-solder. Röntgen photographs show that the solder is gradually absorbed as the bone grows and fills up the cavity. In using this iodoform-solder, in operation, it is poured into the opened cavity, hot, is allowed to harden, and then the operation is continued. Drainage may be left in place. The details of 16 cases treated in this manner follow, with photographs and Röntgen photographs. The results are excellent. Hackmann concludes that iodoform-solder quickly causes healing of carious and necrotic cavities; that it makes healing by first intention more probable, that it increases or stops the discharge from the wound; that it diminishes the chance of recurrence; and that a good clean result. [M. O.]

2.—Trzebicky reports his results in 133 cases of anesthesia by Bier's spinal method. Of these 103 were successful; four were finished with chloroform; and 31 were unsuccessful, 8 times due to technical errors. He concludes that it cannot as yet replace ether or chloroform anesthesia, on account of the danger of infection, especially in private practice; that in institutions where there is little danger of infection, further investigations should be undertaken, in especially adapted cases; that this method is particularly suitable for operations upon the lower extremities and in the pelvis, especially in laparotomy for appendicitis, hernia, etc. But intestinal operations are contraindicated.

Other contraindications are myocarditis and septic or pyemic conditions. [M. O.]

3.—Pendl reports a case of subcutaneous rupture of the patellar ligament, in a man of 42, upon whom he operated a week after the accident occurred. He made an incision lengthwise, laid open the torn ligament, and irrigated the opened joints. The ends of the broken ligament were freshened and sutured with silk. Then, after closing the incision, the knee was put into plaster. Later a support was worn, and massage given daily. Hard masses are now felt in the line of the sutures, which Röntgen photographs show to be bony. Yet they in no way interfere with the patient's movements. Pendl could find but 28 reported cases of suture of the patellar ligament in the literature. Pendl believes that no other operation would secure such a good result. [M. O.]

May 23, 1901. (XIV Jahrgang, No. 21).

1. Theodor Meynert. PROFESSOR ANTON.
2. Alimentary Glycosuria. EMIL RAIMANN.
3. The Juvenile Form of Progressive Paralysis.

JOSEF A. HIRSCHL.

1.—A eulogy delivered at the unveiling of the bust of the late Dr. Theodor Meynert.

2.—After experiments upon healthy men, in whom the assimilation of sugar ingested, measured by the amount of glycosuria resulting, was seen to be variable, Raimann experimented upon diseased individuals. In idiocy, acute mania, paranoia, and in the abstaining alcoholic, the assimilation limit is high; in melancholia, acute dementia, senile dementia, paralysis, and alcoholic delirium, it is low. Among the 103 cases examined were two diabetics, one with dementia, the other with paranoia. Next to these, in the amount of glycosuria following the ingestion of sugar, come the alcoholics. Of the 65 remaining cases, only 14 showed any sugar in the urine, the other 51 being negative. Raimann concludes that the grade of the sugar assimilation is the expression of a general function; it differs in individuals. This sugar assimilation is influenced by a series of ectogenous and endogenous disease poisons. [M. O.]

3.—After a thorough review of the literature, Hirschl describes the full four cases of the juvenile form of progressive paralysis, varying from 16 to 24 years of age. Hirschl has made autopsies upon twelve such cases. He concludes that hereditary syphilis is often the cause of juvenile progressive paralysis; that it appears about puberty, as a rule; that the patients are generally children of deficient intellect; that there is a prodromal stage, rich in symptoms, especially in attacks; that, at its height, the disease is a simple dementia, not paralytic mania or hypochondria; that no remissions occur, though irritation symptoms, movements, attacks, etc., are frequent; that the disease lasts a long time; and that at the autopsy a diffuse sclerosis of the brain with marked leptomeningitis is found. [M. O.]

JOURNAL DES PRATICIENS.

May 18, 1901. (15 Année, No. 20.)

1. Abdominal Massage.

1.—Abdominal massage is above all a great regulator of the general economy by its action upon the general circulation. The patient should lie on a hard bed, with his abdominal muscles relaxed. Before receiving massage, he should urinate. Cautru divides abdominal massage into massage of the whole abdomen, of the intestines alone, or of the stomach alone. Massage of the whole abdomen, which may be superficial or deep, should be given first in all cases. Superficial abdominal massage may be soothing, which is done by skimming over the surface of the abdomen lightly, hand after hand, or by superficial vibrations, the hand of the masseur being kept in one place, trembling from voluntary tetanization of the muscles of the arm. Or superficial abdominal massage may be exciting, which is done by lightly administering taps, pinches, kneading, knocks, etc. Deep abdominal massage is given by pressure with the open hand or closed fist, by kneading, knocking with the knuckles, and by deep vibrations. Massage of the entire abdomen should not exceed 5 or 6 minutes in weak individuals, 15 to 20 minutes in a strong subject. Massage of the large intestine consists of kneading with pressure over the course of the colon. Superficial soothing of the stomach is of use in gastralgia pyloric stenosis, and nervous dyspepsia;

superficial exciting massage is of use in gastro-intestinal atony and hypopepsia, but is contraindicated in gastric ulcer, cancer, gastralgia, etc. Deep massage of the stomach is used either to strengthen the muscle action or to help evacuate the stomach, in dilatation. Abdominal massage is indicated in gastric or intestinal dyspepsia. It is to be employed in hypochlorhydria, and in aepsia, whether due to nervous causes or to tobacco, but is contraindicated when aepsia is due to glandular atrophy or cancer. When gastritis exists, massage will do good. In hyperchlorhydria massage is only indicated if pain exists, and should then be only superficial. In plethoric individuals with hypertension and hyperchlorhydria, deep massage will help, but it is contraindicated in nervous hyperchlorhydria or tabes. In constipation, massage will do wonders. It is also indicated in chronic diarrhea, mucomembraneous enteritis, and chronic typhilitis; but it is contraindicated in appendicitis. Three or four weeks after operation, however, massage of the cecum is very good. With Swedish movements and abdominal massage, gastro-intestinal dyspepsia will be well cured. [M. O.]

May 23, 1901. (15me. Année, No. 21).

1. The Nature of Gout and its Treatment. A. MOREL LAVALLEE.
2. Essential Paroxysmal Tachycardia in Childhood. PIERRE MERLEEN.
3. Death in Typhoid Fever. CHARLES FIESSINGER.

1.—Morel-Lavallée has had an opportunity to examine gouty tophi in a patient under his care, as the deposits increased. These examinations showed that the deposit was composed, not of urates, but of calcium phosphate and carbonate with some calcium sulphate. With this the urine was found hypo-acid, its acidity being but one third the normal. Morel-Lavallée concludes that when hyperacidity exists, the gouty deposits are tribasic calcium phosphate. The treatment should be directed against the cause of the gout, gravel, rheumatism, etc., not against hypo-acidity. This deposit is increased by the ingestion of large quantities of alkalies. [M. O.]

2.—Merklen reports a case of essential paroxysmal tachycardia in a girl of 13, with rheumatic ancestry. She has had three attacks of palpitation, with vomiting and dyspnea, each one more severe than its predecessor. The last attack lasted a week. Under treatment the dyspnea cleared up, but the tachycardia (220 per minute) persisted, after leeches and warm applications had been placed over the precordia. During convalescence there was a striking polyuria. Two weeks later the heart was found perfectly normal. There was dilatation of the heart, with bloody expectoration. The pulse rate fell to 80 suddenly, on the eighth day, normal, but the blood pressure was slightly diminished. The last attack Marklen considers prolonged paroxysmal tachycardia with acute dilatation of the heart. Other cases of this kind in literature show the immediate good effect of applying leeches. The disease often appears first in childhood. [M. O.]

3.—The cold bath treatment prevents death in typhoid fever. Fiessinger believes that deaths from cardiac, pulmonary, and nervous complications are only seen when the bath treatment has been omitted. Hemorrhage and perforation are not stopped by the bath treatment. Saline injections are of great use in hemorrhage, especially when the hemorrhage is small in amount. Fiessinger also uses ice bags when hemorrhage occurs in typhoid fever. [M. O.]

REVUE DE CHIRURGIE.

May, 1901. (21me. Année, No. 5).

1. Fracture of the Base of the Skull. E. QUENU and RENE TESSON.
2. The Late Results of Tarsoplasia with the Osteoclast. E. VINCENT.
3. Accidents Attending the Eruption of the Wisdom Teeth. MOTY.
4. The Treatment of Paralytic Luxation of the Shoulder. BOTHEZAT.
5. The Perihepatic and Pleural Complications of Appendicitis. L. LAPEYRE.
6. Observations upon 1200 Cases of Chloroform Anesthesia. MAURICE BOUREAU.
7. The Treatment of Colostomy. X. DELORE and M. PATEL.

1.—Quenu and Teston report a case of postero-anterior radiating fracture of the base of the skull. An omnibus conductor, aged 49, had been knocked down by a bicyclist, and died the next day. The autopsy revealed a basal fracture of the skull, beginning at the superior angle of the occipital bone, to the left of the median line, the fracture passing along the floor to the left cerebellar fossa, along the petro-basilar suture, through the pterygoid portion of the sphenoid bone. But three similar cases were found after a thorough search of the literature. In all four cases the occiput struck the ground with violence. From experiments upon 10 bodies, this fracture was produced only four times. Thus a special type of fracture exists, a **postero-anterior fracture of the base of the skull**, following a fall upon the occiput, radiating across or around the cerebellar fossa, to the sphenoid along the petro-basilar suture, as a rule, extending even into the ethmoid bone. Direct violence is always the cause, associated with a certain loss of resistance of the bones forming the base of the skull. Hemorrhage occurs, otorrhagia also occasionally, with coma and death. The diagnosis will depend upon finding the line of fracture. [M. O.]

2.—Vincent, who has performed tarsoplasty with the osteoclast (forcible massage), for difficult cases of club-foot, reports the late results of his operations. Out of 204 cases operated eight or more years ago, only 17 have reappeared for examination. The osteoclast molds the tarsus in these deformed feet by force. A description of the instrument, and the supports worn after operation follows. Radiography shows no changes in children. But the effects of tarsoplasty in adults are well shown by radiographs of 5 cases before operation, after operation, and eight or twelve years after operation. The foot-prints are also given. Vincent concludes that tarsoplasty with the osteoclast generally causes lesions similar to those found in a sprain. Fracture is very rarely seen. In no case, even years after operation, was osteitis or arthritis found; both the form and the function of the feet being improved by this procedure. This good effect has continued for years, and will probably be permanent. Operation should not be attempted in infants under one and a half or two years old. And massage and an apparatus must be kept up for years following operation. [M. O.]

3.—Will be abstracted when concluded.

4.—Will be abstracted when concluded.

5.—Purulent pleurisy with appendicitis may exist rarely as a result of metastasis through the blood vessels from the appendix, but is generally a local complication, a **pleural abscess by contiguity**. While the former is found with an infarct on either side, the latter will be upon the right side always, preceded and accompanied by **subphrenic suppuration**. In 13 cases of appendicitis collected from the literature right-sided pleurisy was found post-mortem with subphrenic abscess, showing the extension from the appendix through the diaphragm into the pleura. In three others perihepatic abscess was found with appendicitis, but separate from it. From these autopsies it is plain that suppuration from the appendix spreads up the parieto-colic zone to the liver and pleura. Clinically Lapeyre reports 16 cases of right-sided pleurisy with subphrenic abscess complicating appendicitis. He believes that the extension is not due to either the retroperitoneal cellular tissue or the parietal lymphatics, but to the uninterrupted peritoneum in the retrocolic sinus. This is limited above by the suspensory ligament of the liver; below by the inferior cecal ligament. Thus an abscess will form above or below the liver. Pleurisy will then follow by perforation of the diaphragm, or by the lymphatics transporting the microbes through the diaphragm. There are first the ordinary symptoms of appendicitis, then great pain in the right hypochondrium, with dyspnea, stitch in the side, and cough. When the abscess is below the liver, there may be edema of the abdominal wall, enlargement of the subcutaneous veins, and, perhaps, fluctuation. If the abscess is above the liver, however, there is, as a rule, only marked induration of the right side of the abdomen. The physical signs simulate purulent pleurisy. The prognosis is grave; the diagnosis always difficult. Perihepatic abscess may be prevented by removing the appendix when the appendicitis first appears. The only treatment is immediate operation, with removal of the appendix and evacuation of the abscess. [M. O.]

6.—Boureau reports 1200 cases of anesthesia with chloro-

form, using a compress and adding the chloroform drop by drop, gradually. It was necessary to use a tongue forceps but three times, when syncope occurred. Syncope was seen in but 12 patients, all of whom recovered. Sylvester's method of artificial respiration was employed for them all successfully, although it was kept up for a long time in a case of cardiac asphyxia. Eight of these cases were due to asphyxia two to traction upon the stomach in gastro-enterostomy, one to traction upon the liver in cholecystotomy, and one occurred during the stage of excitement, near the beginning of the administration. Three hundred and seventy-two of the operations were laparotomies, with the patient inclined at an angle of 45°. Cardiac syncope is much less seen in this position. The longest operation lasted almost three hours, when 80 c.c. of chloroform was given. She had but little vomiting, and recovered perfectly. Vomiting, more frequent in women, occurred in about one-third of the cases. Very little chloroform was needed in cases of tumors or cerebral lesions. In some cases anesthesia was begun with ethyl bromide. The few cases of paralysis of the extremities which followed chloroform anesthesia were probably due to the position of the extremities during the administration of the anesthetic. The age of the individuals anesthetized varied from three months to 95 years. Boureau believes that there are no contraindications to the use of chloroform. It is innocuous, if well administered. But a skilled anesthetizer should always administer chloroform. [M. O.]

7.—Will be abstracted when concluded.

BOLNITCHNAIA GAZETA BOTKINA.

May 16, 1901. (Vol. XII, No. 20).

1. A Contribution to the Study of the Toxic Manifestations of the Plague in Man. A. F. VIGOURA.
2. On the Physiological Conditions of Destruction and Conservation of the Ferments of the Pancreatic Juice. E. A. GANICKI.
3. On the State of the Albumin-ferment of the Pancreatic Juice under Various Physiological Conditions. N. I. LINTVAREFF.

1.—Will be abstracted when completed.

2.—Ganicki made a special study of the fact observed in Prof. Pavloff's laboratory that when pure pancreatic juice is allowed to stand in the thermostat for a certain length of time, the digestive ferments become weaker and finally cease to act. This phenomenon is due to the destructive action exerted by one ferment upon the other. A series of experiments showed that the **steapsin** becomes decidedly weaker in its action on fats at the expiration of 20 minutes, and after 3 hours only traces of the ferment can be detected. The addition of bile to the pancreatic juice conserves the activity of the steapsin, while the addition of intestinal juice has the opposite effect. But when both intestinal juice and bile are added the activity of the ferment is greatly augmented, while at the same time its destruction is hastened. This is probably due to the action of the trypsin upon the steapsin, for when egg albumin is added the action of the former is inhibited and the activity of the latter is conserved for a considerable length of time. Precisely the same results were obtained with **amylpsin**. In the case of **trypsin** there takes place at first an augmentation of the ferment, owing to the conversion of the zymogen into trypsin. This is followed at the end of 2 hours by a gradual destruction. The addition of intestinal juice has the same effect on trypsin as on the other ferments. Bile exerts a favorable influence, while the best results are obtained from a mixture of bile and intestinal juice. The addition of egg albumin inhibits the action of trypsin, probably to some more or less stable combination of the two. This supposition, however, is to form the subject for future investigations. [A. R.]

3.—Lintvareff found as a result of experiments performed on dogs with fistulae that on a meat diet the pancreatic juice contains trypsin without zymogen, and is not rendered more active by the addition of intestinal juice which seems to exert rather an inhibitory influence. The addition of bile to such juice exalts its activity. On the other hand when the diet consists of bread and milk only, the reverse takes place; there is more zymogen, and the intestinal juice, and not the bile, stimulates the activity of the ferments. The absolute digestive power of the pancreatic juice on a meat diet is greater than on bread and milk. [A. R.]

British Congress On Tuberculosis

FOR THE PREVENTION OF TUBERCULOSIS.

ABSTRACT OF PAPERS.

The Infectiousness of the Milk of Tuberculous Cows, the Bacteriological Diagnosis, and the Practical Value of Tuberculin for the Extirpation of Tuberculosis Among Cattle. By Dr. Lydia Itabinowitsch, Institut für Infektionskrankheiten, Berlin. The occurrence of tubercle bacilli in the milk of cattle suffering from general tuberculosis, or from tuberculosis of the udder, is a fact established by numerous researches many years ago. Some authors demonstrated experimentally that the milk of cattle suffering from incipient tuberculosis may also be infectious, even if the udder is not affected by the disease.

In the year 1899 it was first demonstrated by Dr. Kemper and myself that tubercle bacilli can also occur in the milk of animals suffering from latent tuberculosis where the disease could only be detected by means of tuberculin. This fact was demonstrated in the same year by Ostertag's observations conducted on mixed milk, and by experiments of Adami and Martin on milk samples of single cows. The animals, in all their cases, presented no clinical symptoms of tuberculosis, but reacted to tuberculin. A further proof was furnished by my last year's observations on the milk supplied to infants in Berlin. No tubercle bacilli were found in the milk taken from cows which did not react to systematically repeated tuberculin tests. On the other hand, the milk from animals which were not submitted to the tuberculin test contained tubercle bacilli, though they showed no clinical symptoms of tuberculosis. My earlier bacteriological studies, as well as those of the latter years, on the milk of animals with suspected tuberculosis of the udder established the following facts:

The detection of tubercle bacilli by microscopical examination of specimens of centrifugized milk sediment is not reliable, as they occur in milk bacteria, which are in regard to the character of their growth, as well as to the effect on the animal organs, very similar to the bacilli found by Koch in butter, and which are very difficult to distinguish from the real tubercle bacilli. These acid-resisting bacteria found by us years ago in the milk of animals suspected of tuberculosis were also found by Kühnau under similar circumstances.

The single and only reliable test of the presence of tubercle bacilli in milk remains the animal experiment. This may be somewhat wearisome when it happens, as it sometimes does, that the inoculated animals show suspicious changes, which call for a new test in order to make the diagnosis positive. Further, the suspected milk must be examined repeatedly, as a single result is not sufficient for the diagnosis.

The presence of tubercle bacilli in the milk is not always proportionate to the disease in the animal, though it is natural to expect tubercle bacilli in the milk when there is extensive general tuberculosis, or when the udder is affected. But the difficulties of a clinical diagnosis, even of tuberculosis of the udder, are so great that not unfrequently cases diagnosed as tuberculosis of the udder prove, on post-mortem and on histological examination, to be cases of chronic interstitial mastitis. On the other hand, the presence of tubercle bacilli was ascertained by microscopical examination of pieces of the udder, as well as by animal test, in cases where there was either no apparent disease of the udder at all, or where inflammation only was diagnosed.

There exists experimental evidence also for the third possibility, namely, that tubercle bacilli are not detected in the milk, even by repeated animal inoculation, while the clinical examination and the autopsy of these cows demonstrated tuberculosis of the udder, and showed clumps of tubercle bacilli in the tubercular interstitial tissue of the mammary gland, though there were none to be found in the ducts galactiferous. Thus we see that the clinical examination alone, without the aid of auxiliary methods, is both insufficient and unreliable as a guide to the discovery of tubercle bacilli in the milk. On the other hand,

the inoculation method, though more certain in its results, has proved too elaborate and tedious a process; and, therefore, we are obliged to acknowledge the tuberculin test as the only reliable and rapid means of diagnosis.

As mentioned above, animals reacting to the tuberculin test only, and showing no clinical symptoms of tuberculosis, may supply milk containing tubercle bacilli. Such animals can just as much be the cause of the spread of tuberculosis among other animals, and chiefly among the young cattle, as animals with grave forms of the disease, for nearly all new-born animals are fed for some time with mother-milk.

The frequency of tuberculosis among calves, as well as the great increase of tuberculosis among swine in recent years (the latter is, in 99 per cent. of the cases, to be ascribed to the tuberculous food), offer the best evidence of the assertion that the use of milk of tuberculous animals is the chief cause of the dissemination of tuberculosis among animals. The test with tuberculin, aided by clinical and bacteriological examination, furnishes us with the surest means for obtaining milk free from tubercle bacilli, as well as rearing cattle free from tuberculosis.

The Alimentary Cure of Tuberculosis, by Dr. Samuel Bernheim, Paris. The author insists on the importance of the alimentary cure of phthisis, and on the place which it should occupy in the therapeutic triad of Brehmer. The necessity for restorative feeding, already proclaimed by former clinical teachers, should, however, be carefully studied, and not put into practice blindly.

It is not sufficient merely to speak to a tuberculous patient and to order him to eat often and much, and to take a very rich diet. Before imposing so vague a regimen, the clinician should take an exact and precise account of the digestive power of the patient, for cases vary in this respect. In some we find defect of acidity, in others hyperacidity; in some excessive dilatation; in others diminution in size; in some total anorexia, in others again an absolute intolerance of food. The author insists on this point, not generally admitted, that the stomach of the tuberculous patient is often the seat of tuberculous lesions, or that it is at least the subject of tonic disorders of bacillary origin. It is therefore useful to vary the means of procedure according to the requirements of the patient.

After having studied this first section, Dr. Samuel Bernheim reviews the different foods most to be preferred in tuberculosis. He studies their richness in nitrogen and mineral salts, and parallel with this general study of foods he brings into relief the principal factors producing excess of katabolism in the patient. The clinician will be able for himself to draw from this clinical and biological study the practical conclusions which have in fact been summed up very precisely. The author states that if the tissues and the debilitated organism are to be repaired as speedily as possible, it is imprudent to exact any considerable effort on the part of the stomach at the commencement. This organ should be protected with "pious care," and not be brutally overworked. No good is served by putting inside of a patient an enormous quantity of food; above all, it is necessary to give him nourishment that he is capable of digesting and assimilating. By commencing this nourishment prudently and methodically we arrive at the stage of tempting the stomach of the patient, and the patient finishes by taking his food himself with relish and benefit.

In conclusion, Dr. Bernheim disapproves of an exclusively meat diet, for although these foods contain a large quantity of nitrogen, they contain a very small proportion of the numerous salts and potent acids so indispensable to the renewal of the body. It is not a question of merely fattening the soil of tuberculous patients; it must also be enriched by the numerous organic salts indispensable to vitality; and to attain this end a mixed diet of nitrogenous and carbonaceous foods is absolutely necessary.

The Uses of Tuberculin, by Dr. Charles Denison, Denver, Colorado, U. S. A. Divided into diagnostic and immunizing or therapeutic. The composition of the glycerine extract and its reactionary effect described. Diagnostic proficiency and observance of technique required in its use.

The method of administration and size of dose for diagnostic purposes. The reaction determined by (1) tem-

perature rise, (2) systemic effect, and (3) local auscultated sounds in affected lung tissue.

The immunizing or therapeutic effect of tuberculin, and reasons why the *direct* method (extracts) is preferable to the *indirect* (animal sera).

Descriptions given of the different preparations: Tuberculin R. (Koch), Tuberculoidin (Klebs), Antiphthisin (Klebs), Tuberculinum Purificatum (von Ruck), Watery Extract (von Ruck). Tables of results, giving the author's ten years' experience with 213 patients, also comparative tables.

A discussion of the *modus operandi* of immunization. Chiefly based upon the theory that the toxins are insufficiently or with difficulty absorbed (during the pre-tubercular and infiltration stages) in order to sufficiently stimulate the healing process. Hence the utility of this form of immunization.

Propositions to be dealt with by Sir John Burdon-Sanderson, Bart., F. R. S. *Sanatoria for Working Men and Women.* 1. In Germany more than fifty sanatoria, affording accommodation for about 4000 working-men, are in operation.

2. The success of the experiment has been such as to afford ground for believing that by the *timely admission* of the consumptive workman into a sanatorium his life may be prolonged.

3. In Germany the funds required for maintaining workmen's sanatoria are chiefly derived from the system of compulsory insurance against illness which exists in that country. It may be assumed that no such system could be established in England. It must, at the same time, be admitted that the expenditure required for the maintenance of the working man when incapacitated by sickness must be principally derived from his earnings; in other words, some form of *voluntary* insurance against disease must be regarded as the best substitute for the compulsory system as it exists in Germany.

4. A system of sanatoria supported by voluntary insurance (as, for example, the Industrial Insurance Societies which exist in this country) cannot be as efficient as a means of diminishing the frequency or spread of pulmonary tuberculosis as a system dependent on compulsory insurance. As regards the individual contributor it would no doubt be more advantageous, because its benefits would not be extended to the inferior class of workmen who are most liable to phthisis. But for the same reasons it would be less advantageous to the health of the community, for in this relation the degree of advantage arising from the prompt removal of an infected person from his dwelling and its insanitary surroundings is proportional to his poverty. A system which would provide for the well-to-do workman, excluding the toiler whose earnings are not more than sufficient for bare maintenance, would be unsatisfactory unless it were largely supplemented by funds derived from other sources.

The Diagnosis of Tuberculosis in Living Animals by Serum-Agglutination. By Professor Arloing, Lyons. Since 1898, the author has been trying to discover the existence of tuberculosis in man and in animals by agglutination effected by the serum of suspected subjects (*des suspects*) and a homogeneous culture of Koch's bacillus in a glycerinated broth, *carefully selected for this purpose*.

Applied to animals of the bovine species the observations, carried out on more than 150 subjects, have demonstrated:

1. That the blood serum of calves from five to eight weeks old does not agglutinate these cultures and does not clear them when in the strength of 50 per cent. (i. e. 50 per cent. serum).

2. That the serum of *healthy* adults agglutinates and very often clears when of 20 per cent. strength, but never completely when of 10 per cent. strength.

3. That the serum of tuberculous adults, with rather rare exceptions, agglutinates and clears completely when between 10 per cent. serum and 5 per cent., and sometimes even when weaker than that.

So that every suspected animal which clears with 10 per cent. serum, a culture that would be imperfectly cleared with 20 per cent. serum from a healthy animal, may be considered as affected by tuberculosis.

4. A diagnostic injection of tuberculin (injection *révéla-*

trice de tuberculine) does not perceptibly modify the agglutinating power of healthy cattle (bovine).

5. Serum-agglutination is therefore a new method of diagnosing tuberculosis in oxen, which can be utilized under any conditions *ad hoc*, especially in cases where recourse cannot be had to the use of tuberculin.

Cacodylate of Guaiacol in the Treatment of Tuberculosis. By Dr. F. Barbary, Nice. Cacodylate of guaiacol, first prepared by M. Rebec and myself, has been used in the treatment of tuberculosis since 1899.

The chemically pure substance, $AS(CH_3)_2O-(CH_2-OCCH_3)$ has been employed in the form of injections dissolved in an oily medium. Every flask of 10 grammes of sterilized oil contains 0.9354 of cacodylic acid, equivalent to 0.05 of cacodylate of sodium and 0.05 of guaiacol.

A flask of the solution is injected every two days, the treatment is then stopped for eight days, and subsequently resumed.

Cacodylate of guaiacol acts:

1. On general nutrition, strengthening the organism by cacodylic acid.
2. On the tuberculosis itself, modifying the soil and bringing about an arthritic evolution by means of the guaiacol.

We have been able to compare the results with those of the ordinary treatment in fifty cases. Combined with hygienic measures it has yielded rapid and lasting results in the first and second stages of the disease.

On a New Process of Skin Excitation in the Treatment of Pulmonary Tuberculosis.—Pneumatic Massage.—By Dr. Breuillard, St.-Honoré les-Bains, France. In this communication the author maintains, in the first place, that excitation of the skin constitutes a therapeutic means of the first rank in the treatment of pulmonary tuberculosis, but that in practice this manipulation is far too much neglected.

After having compared the physiological and therapeutic actions of the principle modes of cutaneous excitation (rube-facients, blisters, chemical and thermal caustics, frictions, hydrotherapy, electrotherapy, and massage), Dr. Breuillard gives reference to massage, the action of which is more certain, and is exempt from troublesome complications.

But well applied massage is too engrossing for the doctor, and necessarily is an exceptional and luxurious method. The results obtained are *artistic*, that is to say, inconstant and variable, and depend on the special aptitude of the masseur.

In view of these considerations the author proposes the substitution of pneumatic massage for manual massage, the former of which he has invented, and the simple working of which he demonstrates by means of an entirely new apparatus.

In a word, according to the author, pneumatic massage, which is easily used, combines the actions of hydrotherapy, of various electrical methods, and of manual massage. It is a new note to add to the scale of physical and natural agents hitherto employed; a note which it seems to him will play a very important part in the treatment of chronic pulmonary tuberculosis.

Typhoid Fever Along the Railroad of Ekaterinino from 1886 to 1899.—M. A. Zausajloff (*Bolnitchnaia Gazeta Botkina*, Vol. XII, No. 4) is of the opinion that an etiologic relation exists between the prevalence of typhoid fever and the consumption of fruits and vegetables. He bases his view on statistics compiled from 1,622 cases. These show that the maximum morbidity occurs between the months of July and October, inclusive, when the consumption of fruits is greatest. The minimum is between May and July. Regarding treatment, he observed that the mortality is less when a restricted liquid diet is employed. Under this regime it reached 8.69%, while with a more liberal diet it was 12.46%. He, therefore, does not agree with the authors who recommend forced feeding. Cold sponging, packing or baths were used in cases of high temperature. Baths were not employed during the second half of the disease, as they predispose to intestinal hemorrhage. Of drugs, benzonaphtol, naphthallin, carbonate of guaiacol and acid drinks, made of hydrochloric or lactic acid, were most frequently employed. The best results were obtained with carbonate of guaiacol in large doses. [A. R.]

New Instruments.

SOME CONTRIVANCES FOR APPLYING CARBONIC ACID DOUCHES FOR THERAPEUTIC PURPOSES.

By A. ROSE, M. D.,
of New York.

A number of letters from colleagues who had read my communication to the Editor of *The Philadelphia Medical Journal*, published in the issue for November 24, 1900, asking a description of the mode of application of carbonic acid gas induces me to describe some of the contrivances to apply the gas. The first apparatus which did good service and which has the advantage over the others that it can be easily improvised, as a rule, with the aid of a nearby living druggist, consists of a bottle, holding a pint or a little less, with a wide neck and a rubber stopper perforated so as to admit a tube, with a nozzle, as the case may be, for nose, rectum, or vagina. A solution of about 6 drachms of bicarbonate of soda in about 6 or 8 ounces of cold water is introduced into the bottle, and 4 drachms of crystallized tartaric acid (if pulverized acid is used the development of the gas goes on too rapidly) are added. The larger these crystals are the better. Instead of the tartaric acid crystals, disks of acid sulphate of soda may

FIGURE 1

be used. The bottle is then closed, and the carbonic acid developing in the water rises through the tube, the nozzle of which has been placed in position. This form of gas generator serves quite well to apply the gas to the nasal cavities, to inflate the rectum and in some instances it can be used to give vaginal gas douches. Gas develops during about 10 to 12 minutes. Its disadvantage is that the current of gas can neither be regulated nor interrupted. When I saw the so-called sparklets by means of which liquids are charged with carbonic acid gas, the idea suggested itself to me to make use of this form of containers of liquefied carbonic acid gas for therapeutical purposes,

FIGURE 2—The accompanying cut shows the contrivance for applying douches. The gas contained in the steel capsule in its liquefied state is freed as soon as the screw is turned and has pierced the capsule. It assumes its original state again, descends through the rubber tube into the rubber bag whence it may be applied passing through another tube, to which a stopcock is attached. By means of this stopcock the gas current can be regulated exactly. While the gas douche is applied to the nasal cavity the patient is to be directed to keep his mouth wide open, in order to avoid intoxication, which might occur if an excessive amount of gas should be swallowed.

poses, and the inventor of the sparklets connected the steel capsule containing liquefied carbonic acid, with an aerostat, by means of which the gas current can be regulated exactly.

The sparklet contains about 1700 cc. of CO_2 . The following apparatus for the generation of carbonic acid gas is devised by the apothecary, Mr. H. A. Cassebeer, of New York, and is, like the aerostat, connected with the sparklet portable in our instrument satchel. It has the advantage over those described that the current of gas can be kept up for 40 minutes in succession. It is the best of the three in such gynecological cases as those described by Demme, and reiterated by me in the letter to the Editor of *The Philadelphia Medical Journal*, above mentioned. It consists of a collapsible rubber con-

FIGURE 3

tainer suspended on three standards, and having a capacity of 1500 cc. This generator is fitted with a screw cap perforated by a small hard pipe to which is attached a 3-inch rubber tube leading to a hand bulb fitted with valves and used to provide a greater pressure in the aerostat directly attached, which furnishes a steady supply of gas. In the tube leading from the aerostat is inserted a hard rubber stop-cock to regulate the flow of gas, and to the end of this tube any desired nozzle may be attached. The method adopted, and which is an inexpensive one for obtaining the gas, is the same as used for the generation of carbonic acid in the Nauheim treatment as devised and prepared by H. A. Casse-

FIGURE 4

beer, and consists of pure acid sulphate of soda compressed into hard discs, and pure bi-carbonate of soda in exact quantities to neutralize. The generator is filled to about 2-3 of its capacity with water, and to this is added one of the discs with a corresponding amount of bi-carbonate of soda to neutralize.

THE BUCCO-ANTRAL ROUTE IN NEURECTOMY FOR
THE RELIEF OF TIC DOULOUREUX.*

By GORDON KING, M. D.,

New Orleans, La.

Professor of Laryngology, Rhinology and Otolaryngology, New Orleans Polyclinic,
Senior Assistant Surgeon, Ear, Nose and Throat Department of the
City of New Orleans General Hospital, Fellow of the
American Laryngological Association, et c.

Of the various forms of neuralgia affecting the sensory nerve trunks or their terminal branches none causes more atrocious suffering, is more rebellious to ordinary means of treatment, and is more long lived than that affecting the trifacial nerve, and accompanied by spasmodic contractions of the facial muscles, designated by the French as "tic douloureux," and also known as epileptiform neuralgia. This severe variety of trifacial neuralgia has long been classed among those diseases which are but rarely amenable to medicinal treatment and which require surgical procedures for their relief. While sometimes, in its milder form, the distressing symptoms may be greatly mitigated by the administration of proper constitutional or local remedies, the effects of such treatment are more often but palliative or entirely negative, and after the long list of antineuralgic and anodyne drugs at our disposal have been tried and found ineffectual, we must turn, as a final resort, to surgical measures to afford relief to the unhappy patient.

According to Bruns (*Neurol. Centralblatt*, 1897), genuine tic douloureux is situated in the second and third branches of the fifth nerve and rarely in the first, and he claims that surgical treatment is invariably necessary. As this is the generally accepted theory, where the neurosis is considered of peripheral origin, operative measures should be directed to these branches.

Stretching of the nerve trunks, and subcutaneous division or resection of the nerves at their points of emergence from the bones of the face are methods inadequate to give more than brief temporary relief, and are to be discarded in favor of the more radical operations directed towards resection of the nerve trunks as near to their foramina of exit from the cranial cavity as possible, in inflicting the least amount of traumatism on the patient, and in avoiding unnecessary unsightly scars on the face.

Carnochan, in 1851, is credited with being the first to perform resection of the superior maxillary nerve at the foramen rotundum with success. His method consists in exposing the infra-orbital nerve at its foramen, following it up along the floor of the orbit, and resecting the trunk in the spheno-maxillary fossa in the neighborhood of the foramen rotundum. This operation entails a certain degree of traumatism to the orbital contents, opening of the antrum externally, the formation of a scar upon the cheek, and does not allow of free access to the spheno-maxillary fossa.

The operation of Lucke, or the modification of Lucke's method by Braun and Lössen, is designed to gain freer access to the round foramen, and consists in a temporary resection of the malar bone. The two methods differ only in the external incision

and in the fact that Lucke displaces the malar bone upward, and Braun and Lössen downward. The chief objections to this operation are the great amount of traumatism inflicted and the resulting ugly scar on the face. It was in view of these disadvantages that Alexander Fraenkel, of Vienna, sought a simpler and less difficult route to reach the nerve trunk without scarring the face.

Having observed in Zuckerkandl's anatomical laboratory the method employed for demonstrating the course of the superior maxillary nerve, which consists in exposing it in the antral cavity by an opening in the canine fossa, he was led to attempt its surgical resection by this method. After practicing the operation first on the cadaver, he applied the method to a patient who had suffered a relapse of neuralgia after an operation performed a year and a half previously for division of the terminal of the nerve at the infra-orbital foramen. As described in the *Centralblatt für Chirurgie*, March, 1899, the Fraenkel method is as follows: An incision is made through the mucous membrane of the mouth, beginning over the root of the canine tooth and extending backwards along the gingivo-labial fold to the tuberosity of the maxilla. The lip and cheek are strongly retracted upward, exposing the anterior bony wall of the antrum of Highmore in the canine fossa. This wall is then broken through with a sharp chisel and the bony plate and its internal mucous lining raised in the form of an osteo-mucous flap. This opening brings the interior of the cavity plainly into view, and when the bleeding is checked and all blood clots carefully cleaned out, artificial light is thrown into the cavity by means of a head reflector or a Clar head lamp and the roof of the antrum closely inspected. The infra-orbital nerve can be traced in its course along the infra-orbital canal, which sometimes projects prominently into the antral cavity, or may be seen in its posterior aspect through the thin plate of bone forming the floor of its canal. This canal is then broken into with a small chisel and the nerve drawn out of its bed by means of a short blunt hook, and used as a guide in cutting away the upper posterior wall of the antrum to gain deeper access to the trunk in the spheno-maxillary fossa. The nerve is seized with a forceps, put on the stretch, and divided as near to the round foramen as it is possible to reach, and that portion cut away which has been left exposed in the antrum. The antral cavity is dried out thoroughly, the osteo-mucous flap replaced, and the buccal wound sutured, a small strip of iodoform gauze being left in one angle of the wound as a drain.

This method, as may be seen, is simply a modification of the old Carnochan operation, but its advantages over that procedure are, to my mind, plainly in evidence. Access to the cavity of the antrum, even in its deeper parts, is, to one experienced in the surgery of that region, quite as easy through the canine fossa as through the cheek, and having as an advantage of no mean importance the avoidance of any disfiguring scar or depression about the face. The nerve is readily accessible and can be dislodged and resected without disturbing in the least the contents of the orbit.

The general plan of the operation is similar to

*Accepted as Candidate Thesis for Membership in the American Laryngological Association at meeting held at New Haven, Conn., May 27th, 1901.

that advocated by Caldwell and Luc for opening the antrum in the treatment of empyema of that cavity. My experience with this latter operation had so familiarized me with this route of access that I readily accepted the feasibility of the plan recommended by Fraenkel for neurectomy of the second branch of the trigeminus in obstinate neuralgia, and when two such cases came under my care I did not hesitate to advise and perform the operation so highly extolled by that author. Before applying it to my patients, however, I performed the operation on the cadaver and was agreeably surprised to find how very easy it was to carry out the technique of the procedure and to approach quite near the round foramen to divide the nerve trunk.

The cases which form the subjects of the two following observations have afforded a practical demonstration of the facility as well as the utility of this operative method in the surgical treatment of severe and obstinate forms of trifacial neuralgia affecting the superior maxillary division.

Observation 1.

S. H., a farmer, aged 62 years, a native and resident of Louisiana. His father was a strong and vigorous man and died at the age of 70 from dysentery. The mother reached the age of 40 years and died of causes unknown to the patient. Two brothers and two sisters of the patient are alive and in good health; one sister and three brothers are dead. The man himself was in excellent health up to fifteen years ago, when he experienced the first symptoms of his neuralgic affection. No history of syphilis could be obtained, and, although residing in a malarious district, the patient had never had an attack of malarial or typhoid fever. He had gone through the civil war as a soldier, was accustomed to exposure, and given to hard labor in the fields. In 1885 he suffered an attack of rheumatism, which, according to his statement, began in the right foot, and, ascending up the right side, attacked the shoulder joint and the neck, and ended in a neuralgia of the right side of the face. This passed away for a time but recurred at regular intervals, becoming gradually more frequent and severe and interfering greatly with his daily work. These attacks seemed to resist all palliative treatment given him, but finally subsided somewhat, and for three years he had some relief and was able to carry on his farm work. At the end of that time, however, the pains returned and grew frequent and regular in their recurrence, accompanied by spasmodic twitchings of the facial muscles. Thinking that perhaps the teeth were the cause of the trouble, he consulted a dentist who proceeded to extract four teeth of the upper and six of the lower jaw. This afforded relief of but short duration, and after three weeks the attacks recurred with ever increasing frequency and severity. At various times he applied to his family physician for relief and numerous antineuralgic remedies were tried without affording more than slight temporary benefit. For eight months previous to coming under my observation the patient had been suffering intensely, paroxysms of sharp lancinating pain coming on every five or ten minutes, lasting a few seconds and passing off to recur upon the slightest effort to talk or masticate. Life became burdensome, sleep of more than a few minutes at a time was impossible, and he had become weak and thin from want of rest. I saw him first early in January, 1900, and judged from his history that operative interference alone would give complete relief. At that time the paroxysms were very frequent and intense, but in the intermissions of a few minutes between them no pain was felt and no sensitive points could be detected about the face. The pain was traceable to the distribution of the second and third branches of the trifacial of the right side. His temperature was normal and urinalysis showed nothing abnormal.

January 4th, patient was sent to the New Orleans Sanitarium and the following sedative mixture ordered given every hour until some rest was obtained: Codeine Sulphate gr. 2-3, Antikamnia and Sulfonal, of each, grs. v. Light diet and mild saline purgation was also ordered. One week of this regime modified the attacks to the extent that he

was enabled to gain a little sleep and rest, but it produced no effect upon the disease, as shown by renewed attacks whenever the sedatives were suspended for a few hours.

January 11th, the patient was prepared for operation, as I had decided to resect the superior maxillary branch of the trifacial by the Fraenkel method, and at the same sitting remove the inferior dental by trephining the inferior maxilla. Accordingly, under chloroform anaesthesia, an incision was made through the gingivo-labial fold and the antral wall exposed. The periosteum was detached and elevated to lay bare the infra-orbital nerve at its exit from the foramen the nerve being separated from its attachment to the soft tissues of the cheek and caught up with a hemostatic forceps. The anterior wall of the antrum was then broken through with a chisel and the bone cut away as high up as the infra-orbital foramen, so as to bring the interior of the cavity into plain view when the lip and cheek were retracted forcibly upwards. By making traction on the nerve its bony canal could easily be traced in its course between the roof of the antrum and the orbit, and broken into with a small chisel. Thus the nerve was freed from the canal and followed up into the sphenomaxillary fossa, where it was firmly grasped with a narrow bladed forceps and drawn out by a twisting motion. It parted almost at its exit from the foramen rotundum. This done, the antrum was carefully dried out and the buccal wound sutured with catgut. Attention was then turned to the inferior dental branch, which was exposed at its entrance into the inferior dental canal by trephining the inferior maxilla externally just at the angle. About an inch and a half of the nerve was removed and the skin wound closed. The time required for the two operations, including the administration of chloroform, was one hour and a quarter. Later the patient took some liquid nourishment and passed the first restful night he had experienced for years. An occasional slight twinge of pain in the right side of the face was the only vestige remaining of his painful affection, and that disappeared entirely after the first twenty-four hours. A mouth wash of Seiler's solution to be used every two or three hours was the only after treatment prescribed. With the cessation of all pain and with the ability to sleep peacefully, and to talk and eat with comfort, the man grew cheerful and began rapidly to regain his strength. One week from the date of operation he left the sanitarium and returned to his home in the country. A careful examination before his departure showed the wounds well healed, entire absence of the spasmodic pains, and anesthesia of the skin of the right side of the face corresponding to the area of distribution of the two resected nerves. Two months later a letter from the patient informed me that he had gained twenty-five pounds in weight and felt well in every respect. The following December his family physician wrote me that the patient had come to him to report that, as a result of over-exerting himself while at hard work in the field, he had experienced some slight pain in the face of a spasmodic character. It was not severe enough to interfere with his eating or sleeping, and he reported it simply because he had been instructed by me to do so should he, at any time, have neuralgia of that side of the face. I wrote advising him to strictly avoid heavy labor and over-exertion, and have since received encouraging reports from time to time. As late as May 1st, of this year, he was still enjoying good health and only felt faint paroxysms of pain when he was imprudent enough to over-tax his strength.

Observation 2.

Mrs. O. L., 53 years of age, a native of Louisiana, and a near neighbor of Case No. 1, and in many respects a case of similar nature. She was referred to us by her family physician who had long before exhausted the medicinal remedies at his command in a vain endeavor to prevent the frequent agonizing paroxysms of neuralgic pain to which the unfortunate woman had been a victim for the past seven years. She had always been a hard working, vigorous woman until her strength had given way for want of rest, and she was no longer able to perform her household duties and had grown morose and despondent. The pains followed the courses of the superior and inferior maxillary divisions of the right trifacial, the latter branch being only recently affected. The paroxysms were accompanied by salivation and contractions of the facial muscles, in fact, a typical case of *tic douloureux*. The cheek appeared to

be a little sunken on the affected side, showing some trophic change in the muscles. A thorough examination failed to reveal any reflex cause of the affection, so resection of the superior maxillary and inferior dental branches was proposed. She was admitted to the Sanitarium June 15th, 1900, to be prepared for operation on the following day. Urinalysis revealed nothing abnormal.

June 16th, patient was taken into the operating room, and under chloroform anesthesia, the usual incision was made in the gingivolabial fold down to the bone, and the periosteum and cheek retracted upward to reveal the nerve at the infra-orbital foramen. The anterior wall of the antrum was then broken into with the chisel and freely enlarged with rongeur forceps as high up as the infra-orbital foramen and backward towards the tuberosity. The nerve was divided at the foramen, its canal along the roof of the cavity laid open throughout its entire length, and the upper posterior wall of the antrum broken through into the sphenomaxillary fossa. The trunk of the nerve was caught in this situation with a hemostatic forceps and twisted out, almost two inches of the nerve being thus removed. All bleeding in the cavity was completely checked and loose pieces of bone removed, and then the periosteum and mucous membrane caught up and closed over the breach in the anterior wall with catgut sutures.

The inferior dental was next exposed by trephining the maxilla at the angle, and drawn out of its bed with a tenaculum. The distal end came out readily upon traction with a forceps, parting as far anteriorly as the mental foramen, and then about one-fourth of an inch more was brought out by twisting the proximal end. Some hemorrhage occurred at this point from injury of the accompanying artery, but was easily controlled by compression. The patient took the anesthetic rather badly and vomited frequently, which delayed the progress of the operation to some extent. One hour and a half was consumed in completing both operations. The patient slept at intervals during the night that followed, but was frequently disturbed by the persistent nausea, experiencing, however, no more attacks of facial pain. Convalescence was rapid and uneventful, and at the end of a week she was permitted to leave the Sanitarium and return home. The area of cutaneous anesthesia extended over ala of nose, right side, over cheek to lower margin of the orbit, right half of upper lip and gums. The tongue and inner surface of the cheek were sensitive to the prick of a pin.

Recent news of the patient inform me of her improvement in general health and, as yet, no recurrence of the neuralgia.

In operating on these cases I saw fit to modify the method advocated by Fraenkel in such manner as to both simplify the procedure and to resect a greater length of the nerve, while at the same time to assure complete closure of the buccal wound by dispensing with the gauze drain. After incising the mucous membrane and periosteum covering the anterior wall of the antrum, I elevate the periosteum as high up as the infra-orbital foramen, divide the nerve at this point, and open the entire canal into the antrum. This dispenses, in a measure, with the necessity for a very strong light to illuminate the cavity in order to recognize the situation of the nerve in the deeper parts.

I find, likewise, no special advantage in preserving a bony flap, provided the periosteum is well sutured over the opening made in the anterior wall, as no depression of the cheek results from the deficiency of the bone. The opening should be made large enough to permit of easy manipulation within the cavity.

I have found it expedient to remove the nerve by twisting and avulsion, as advocated by Thiersch, instead of cutting through it; for this insures extraction of a greater length of nerve and division of those branches that are given off in the sphenomaxillary fossa.

Experience has also taught me that the healthy lining membrane of the antrum shows strong resistance to infection from surgical wounds, and that a gauze drain is not necessary, but even harmful, when proper precautions are already taken for asepsis and arrest of hemorrhage before the cavity is closed. A strip of gauze left in the wound as a drain may lead to the formation of a fistula into the mouth and subsequent infection from that source. If any symptoms of infection within the cavity appeared in the course of healing, irrigation through the hiatus could be practised.

As but slight traumatism is inflicted by the operation, the inferior dental branch can be excised at the same sitting, as was demonstrated in the above cases. While neurectomy of this nerve by trephining the maxilla necessitates scarring the face, the scar is merely linear and in men is less noticeable or entirely hidden by the growth of the beard. The functions of the tongue and the muscles of mastication are not weakened when the nerve is cut at this point.

In conclusion, I desire to enter a plea in favor of the extra-cranial resection of the nerve trunks in cases of obstinate trifacial neuralgia, to be proposed as a test treatment always before such dangerous operations as are required for resection of the Gasserian ganglion are attempted. While we know that in many cases recurrence comes on within a few months or years after a peripheral operation has been done, and resection of the ganglion is a last resort, such is not necessarily the case, and permanent, or at least temporary, relief is obtained by this simpler and less dangerous method.

A CASE OF TIC DOULOUREUX, WITH SUCCESSFUL REMOVAL OF THE GASSERIAN GANGLION—WITH PHOTOGRAPH OF THE PATIENT.*

By HENRY T. WILLIAMS, M. D.,

of Rochester, N. Y.

Surgeon to Rochester City Hospital and St. Marys Hospital.

The history of the case is as follows:

Mrs. M. Housewife, 38 years of age, born in New York State. Has had three children, aged 10, 7 and 2 years; aside from two attacks of severe tonsillitis when she was 15 years of age, has been in good health up to the birth of her first child, when she had puerperal fever, confining her to bed for several weeks.

Family history is good; her father died of old age, mother is still alive and well, 2 brothers died in infancy and 2 brothers and 2 sisters are still living and in good health.

Her first attack of neuralgia occurred about 10 years ago; began about 2 months before birth of her first child; she suffered with severe neuralgia of right side of her face until after the birth of her child, when it disappeared for 18 months; she again became pregnant and the neuralgia returned and lasted nearly continuously until 1893; when she came to Rochester and was operated upon by Dr. J. M. Lee, who she states divided the nerves on the right side of her face (there is a scar about one and one-half inches long, extending from below the zygoma to near the angle of the jaw); this gave her relief for 4 months, but the pain again returned and she had difficulty in masticating her food, or even talking; every effort at moving her jaw

*Read at a meeting of the Rochester Academy of Medicine, April 10th, 1901.

causing excruciating pain; nearly all of her teeth were extracted, but it gave her no relief; in the fall of 1894, she was again operated upon by Dr. Lee, who I understand stated that he removed the superior maxillary ganglion, this gave her no relief whatever; in 1896, she was operated on in the same location, by another surgeon, who rephined the inferior maxillary bone, but this gave her no relief. In 1897 she again became pregnant and the pain became very much less and she was quite comfortable for 3 months, when the pain again returned with increased severity, so that she was confined to her bed most of the time and was unable to sleep or walk around or eat, except when under the influence of anodynes; could only open her mouth a very little way and could eat only soft food, and that with great difficulty, owing to the pain.

Patient with Tic Douleureux.

She came under my care and entered the City Hospital August 11th, 1899. At Dr. Roe's suggestion, I examined her nose and finding a deflected septum and a spur of bone, I removed the spur and straightened the septum; this gave her no relief at all and on August 30th, 1899, I made a curved incision with its convexity upward, after the House-Hartley method, in the temporal region above the zygoma, and after partly turning down the skin and muscle I chiseled through the skull with a small grooved chisel, following the line of incision outward with a strong bone elevator, the section of bone was removed by cracking it across the base with a few blows with hammer and chisel and the dura exposed, the section of bone remaining attached to the skin and muscle flap; the dura and brain were next separated by the finger from its attachment to the skull, the temporal speno lobe of the brain was lifted up by a long retractor and the nerves were divided; the bone was replaced and the skin flap united by catgut sutures; no relief being experienced, the pain returning as soon as the patient came out from the influence of the anesthetic, I again operated upon the patient, three days later, viz: on September 2, 1899. This time I opened up the previous incision and in order to make a more room, another flap was made posterior to the first and quite a little larger, and after the bone had been

chiseled through, the flap (including the bone), was turned up; this made a larger opening and the incision through the skin was an "S" shaped one, with the letter "S" lying on its face; one flap of bone being turned up and the other down. The dura and the temporal lobe of the brain were lifted up with long retractors; the layer of dura covering the Gasserian ganglia and superior and inferior maxillary division of the trifacial nerve was divided and turned either side exposing the nerves and ganglia; about one quarter of an inch of each nerve was resected, and the distal ends of the nerves were pushed through their foramina with a probe; the proximal ends of the nerves, with the Gasserian ganglia were scraped out with a small curette and a probe was passed into the Gasserian fissure and the fissure well scraped with it; during the operation the two pieces of bone removed, became loosened from the skin and muscle flaps and were found on the floor, they were picked up, and placed in salt solution for a while and were then replaced and the wound in the scalp sewed up with catgut. The operation took 1 hour. Primary union took place and patient left the hospital in 18 days, well. Patient was entirely free from pain and could open her mouth wide without pain as soon as she recovered from the anesthetic, and 4 days after the operation she was allowed to eat solid food, and experienced no pain. The last time I heard from her (which was several months after the operation), she was still well and free from pain.

DIAGNOSIS AND PROGNOSIS OF HEART DISEASE.*

By M. H. FUSSELL, M. D.,

of Philadelphia.

Assistant Professor of Medicine, University of Pennsylvania.

When your secretary asked me to address you this evening on the subject of Diagnosis and Prognosis of Heart Disease, I at once remembered an occurrence of my early medical life which has had much to do with my present view of heart lesions.

From 1885 to 1889 I had the great privilege of being the clerk of Professor Osler, in the Medical Dispensary of the University of Pennsylvania. Among my duties was the preparation of notes of dispensary cases for use in Dr. Pepper's clinics. On one occasion I wrote out and reported to Dr. Pepper the notes of a case of grave diabetes mellitus. After the history of the case came the physical signs. I had written "Heart's action rapid, but heart sounds normal." When the great clinician came to "Heart's sounds normal," he omitted the words, and examined the patient. He pointed out to the class the extreme weakness of the muscular element of the first sound, causing it to resemble closely the second sound in character. He laid much stress upon the fact that, because there was no murmur present, was no reason to believe that the heart itself was in a normal condition.

That one lecture by Prof. Pepper taught me what I had never before realized, a fact which I believe many general practitioners to-day do not realize, namely, that while heart murmurs are signs of cardiac lesions which are never to be ignored, the mere presence or absence of an adventitious heart sound is of relatively small value in the diagnosis or prognosis or treatment of heart disease.

In my observation of the heart cases I have had the opportunity of studying, it has appeared to me that no accurate diagnosis or prognosis and consequently no proper or efficient treatment can be undertaken in any lesion of the heart—indeed, in any disease—unless the observer has availed himself of the four cardinal principals of physical exam-

*Delivered before the Germantown Medical Society, May 13, 1901.

ination: Inspection, Palpation, Percussion and Auscultation. I fear that the latter means of arriving at a diagnosis of heart disease is the only one frequently used. How valuable it is when used in conjunction with the other helps and how little it can be depended upon when used alone shall be my endeavor in this evening's address.

Inspection.—By inspection I do not mean the causal view of the region of the apex beat of the heart, but a view of the entire body of the individual, his facies, the line of his peripheral vessels and the cardiac region. If the patient's face is anxious and pale or cyanosed, we may be well assured that the circulation is interfered with either by some extraneous cause or by some weakness in the heart muscle itself. An undue pulsation along the line of the great vessels means—a nervous condition, an anemia, an atheromatous condition of the vessels, or some grave heart lesion.

A diffuse wavy impulse seen over the cardiac area means an anemia, a nervous disturbance or cardiac dilatation.

Palpation.—Embracing not only the cardiac region, but the blood vessels, gives evidence as to the rapidity of the heart's action, its regularity, the presence or absence of a thrill over the cardiac region. The synchronous action of the heart and the arterial pulse must also be observed, and this is important for more than once it has fallen to my lot to observe a radial pulse of 60, regular, full and moderately strong in an individual whose heart was pulsating regularly 120 times to the minute. So weak was every other systole of the heart that only sixty were recognized by the finger on the wrist.

The condition of the peripheral vessels themselves is a most important element in diagnosis and prognosis, and can only be told by palpation or guessed at by inspection.

Percussion.—The area of cardiac dulness is a most valuable sign. The normal area of the cardiac dulness is certainly different within certain limitations to different equally competent observers. For myself, I place the normal area of deep cardiac dulness at the third interspace above, midsternum or left border of the sternum to the right, never farther to the right than mid sternum, and just inside of the mid clavicular line to the left. Variations from these lines, if greater, mean either hypertrophy dilatation, or displacement of the heart.

Auscultation.—It appears to me, as I have already stated, that the most valuable sign we get from auscultation is the condition of the heart muscle, as revealed by the character of the first and second sounds of the heart.

The familiar sounds you all remember, as demonstrated time out of memory of lub-dub, are not far wrong for normal heart sounds. The first, "lub," being made up of contraction of heart muscle, of impact of heart against the chest wall and of valve sound.

In cases of dilatation, of degeneration of the heart muscle, in some cases of anemia, the first loud, muscular sound disappears and leaves in extreme cases a mere valvular flap itself often inaudible. This I repeat again, is to me the most valuable single sign, for its appearance means some change in the heart itself, a dangerous condition. If the first sound, on

the other hand, is strong and full, it matters little for the time being whether a murmur is present or not.

Lastly, Murmurs—of which I shall speak later—are always most valuable signs of heart disease, because they frequently show the presence of a valvular lesion which will sooner or later lead to degeneration of the heart muscle.

It must never be forgotten, however, that murmurs so loud that they rival an organic lesion in intensity often are due to blood changes or some other condition entirely independent of the heart itself.

The following case will illustrate the fact well:

In my first year of practice I was called to see a girl of 16 years—pale, weak—with general edema, irregular pulse and loud murmurs over the body of the heart. I announced to the family that we had to deal with an organic heart disease, and that the anemia was the result of this disease. I fortunately put her upon Bland's pill. She promptly recovered, and with her regained color her heart murmurs disappeared. She is now, after 15 years, a buxom woman of 31, without a trace of heart lesions.

Of course, I have long since recognized that I treated a case of chlorosis, and that no heart lesion was present, but no amount of argument will convince the family that the patient did not have heart disease of which I cured her.

These remarks may appear to you extremely fundamental, and anything but original, but I am quite certain that it is only by a repeated application of these principles in every case that will save us from the practice of the digitalis or digitalin man who gives these drugs whenever he hears a heart murmur independently of the condition of the heart muscle, or every time he feels an irregular pulse independently of its cause. And it will save our patients from the untimely death which must come to many so treated.

Let us now concern ourselves with some of the specific heart lesions. It will not be possible for me to speak of the heart conditions of systemic states, which so closely resemble organic lesions of the heart itself, but I have decided to confine myself to those conditions in which the heart itself is organically affected.

Fibroid or Fatty Degeneration of the Heart.—(For present purposes one need not distinguish between the two.) In discussing these most important of all heart lesions, one which is easily recognized in its later stages, but constantly escapes detection in the vast majority of cases until the patient is in great danger of death if not entirely beyond hope of material betterment, the doctor, the family doctor, must bring into play the very essential physical examination for which I have been pleading. I say the family doctor, for it is to him the sufferer first applies with ailments which seem to him trifling. It is the doctor alone who can, if he takes the trouble and has the experience, recognize the first stages of the general fibroid change, of which I take it, the heart lesion is but one, though perhaps the most dangerous lesion, as it is certainly the lesion which gives rise to the most annoying symptoms. The history of such a case is usually as follows: An individual reaches thirty, forty or fifty years of age. He may be a man most exemplary in his habits, a man of

large business or professional interests, who works without ceasing from early morn until late at night, he eats hurriedly all his meals, which consist of anything his taste chooses, very likely taking considerable alcohol to strengthen him while never becoming intoxicated in the least degree. He may be an alcoholic who from early years has either been a drunkard, or, what is still more potent in causing his condition of general fibrosis, taking a number of drinks of spirit daily, frequently on an empty stomach; syphilis may have been contracted and be the cause of his symptoms. These symptoms are about as varied as the number of patients—in very early stages. Vertigo, annoying but not distressing, a tendency to shrink duty in an individual with ambition for work, a slight dyspnea on exertion, an occasional fluttering of the heart, a halt in the pulse, the patient passing proportionately more urine of lower specific gravity than normal.

Later in the stages of fuller or complete development there is distressing dyspnea with much vertigo, cardiac pain, much palpitation of the heart, inability to sustain any prolonged exertion. It is in the early stages when good may be done, by regulating the mode of living, if not by drugs, by the limitation of work and cutting down the amount of alcohol if not advising its total disuse.

The physical signs of such a condition are a pulse which is of high tension, which lingers long under the finger, and which may deceive the unwary by its semblance to a full, strong pulse originated by a strong heart, the arteries may or may not be atheromatous, depending upon the amount of degeneration. The apex beat instead of being forcible and strong, as should be by a pulse of good quality—is weak, may not even be felt with the patient lying down or may not be felt at all. The heart dulness is a little too great, extending somewhat further to the left than normal. The degree of this enlargement depending upon the amount of hypertrophy of the wall due to fibroid change or to degree of dilatation. The heart sounds are abnormal in that the first sound lacks much of its muscular force, and resembles much more closely a second sound. The second sound is distinctly accentuated at the aortic cartilage. In advanced cases the first sound is inaudible at the base of the heart and at the apex is a mere valvular tap, the second sound being often the louder and constantly mistaken for the first sound by the medical student. Usually the cardiac dulness in these advanced cases is too far to the right as well as to the left on account of the dilatation of the heart.

No murmurs are heard except in late stages, when the adventitious sound is due to dilatation or in some cases roughing of the aortic orifice or valve. It must always be remembered, however, that these murmurs are entirely secondary in importance to the valuable signs of dilatation. The urine is apt to contain albumin and perhaps a few casts. If it does, the case is looked upon often as one of Bright's disease simply, and is ill-treated.

My plea is to view these cases early, to observe the changes going on in the peripheral vessels and the heart wall, and endeavor to stop the process at least delay its deadly course.

I shall now briefly refer to cases of endocarditis which are the set of cases mostly termed heart dis-

ease, because they are essentially primary lesions of that organ, other organic changes being secondary to the heart lesion. In these cases I repeat at the risk of tautology the important signs are the condition of the muscle wall, rather than the murmurs which attract attention and are so interesting and instructive. It is of the utmost importance to the proper treatment of our patients that all endocardial murmurs shall be detected—for the reason that these murmurs are an index as to what is fairly certain to occur in the lifetime of the patient. I want to repeat what I have already said more than once, that the mere presence of a cardiac murmur is not an indication that the patient needs digitalis or other cardiac stimulants; such drugs should be used only when signs of dilatation and failing compensation appear.

It will be of value to consider the different valve lesions somewhat in detail, those occurring at the aortic orifice, and at the mitral orifice. Time will not permit me to speak of lesions of the right side nor of pericarditis.

The rules which I have laid down in speaking of fatty or fibroid degeneration are applicable here in the highest degree. We should always begin our observation by inspection, palpation and percussion, and round out our examination by auscultation.

The attractiveness of heart murmurs is so great that being once heard one is apt to think only of the murmur and not of the lesion in the heart which the valve condition has brought about. I think I have yet to direct a student to examine a heart who has not as his first act, taken out his stethoscope—listened anywhere over the body of the heart, if there was no murmur, sat down and said the heart was normal. Therefore, I plead for the order of examination which I have already stated.

Having then satisfied ourselves of the rapidity and regularity of the heart beat—of the presence or absence of a thrill, etc., and of the size of the heart, we auscult. A murmur may be heard at the aortic cartilage, which is conducted into the vessels of the neck. The murmur may be very slight, low pitched and scarcely heard or so loud that it drowns all the normal elements of the first sound. If it is not due to a blood change or functional cause, it means one or two things. Either there is a roughness of the aortic orifice or of one of the aortic valves *without stenosis* of the aortic opening; or it is due to true mechanical obstruction of the aortic orifice aortic stenosis. The first is a condition which may exist during the rest of the patient's life, and never cause any disturbance, or it may be due to the general fibroid change going on in the patient's system.

The second condition, that of aortic stenosis, is one of the gravest primary heart lesions. If the murmur is due to a simple roughing of the aortic orifice, the heart's action will be regular, full and forcible. The muscular element of the first sound unchanged, there will be no change in the second sound of the heart. The heart dulness will be normal. If, on the other hand, the lesion is due to actual stenosis of the orifice, the first sound of the heart may be unusually loud and strong, owing to the hypertrophy of the heart, the cardiac dulness

will be greatly increased to the left, the apex beat often being in the sixth interspace. The right side will be unchanged unless the case is so advanced that dilatation is taking place, when the area of cardiac dulness will be increased also to the right. The radial pulse will be small.

The vast majority of systolic murmurs which are heard at the aortic orifice are due simply to aortic roughening and not to any true valve change. They are often only a senile change, but may be of great prognostic value, as shown by the following case, of which I could quote duplicates:

A lady of good family was seen by me some eight years ago suffering from neurasthenia. Notes made at the time of the examination show that at that time her heart was perfectly normal. In the course of two or three years she developed a systolic murmur at the base of the heart. There was no change in the size of the heart nor in its rhythm for two or three years more. Two years before her death she developed a murmur in the mitral region, indicating a valve change there. At the end of another year she showed signs of cardiac failure and died in a few months thereafter of that condition.

In this case I am convinced that the murmur which developed first at the aortic cartilage was the first indication of a slowly developing endocarditis. Since that time I have been most suspicious of such murmurs occurring under observation in an otherwise normal individual.

Usually, however, I repeat, a murmur heard at this region is indicative usually of some atheromatous change rather than an endocarditis and does not call for treatment unless other physical signs are present.

Another change at the aortic orifice is that of *aortic regurgitation*. This condition is much more common than aortic stenosis, and when fully developed there can be no question as to the condition present.

There is great hypertrophy of the left ventricle. The apex beat is diffuse, and felt often in the sixth interspace outside of nipple line. The right side of the heart is but little changed unless dilatation is taking place, when the line of cardiac dulness extends to the right of the sternum. There is a long drawn usually high pitched murmur with the diastole, which is conducted down the left edge of the sternum toward the xyphoid cartilage. The murmur is best heard often at the left third interspace near the sternal line. The peripheral vessels pulsate markedly, and there is usually a water hammer pulse. That is a quick full pulse of low tension.

Such cases are, as I say, usually easily diagnosed. They are to be distinguished principally from aneurysm of the arch of the aorta, in which condition there may also be a diastolic murmur. There is usually, however, an abnormal dulness under the sternum in aneurysm. The murmur in aneurysm, I believe, is best conducted down the *right* side of the sternum instead of the left. There is relatively little hypertrophy of the heart. In this condition again I think a diagnosis is of the utmost importance that the habits of the patient may be so regulated that he may establish a proper compensation and not bring about a dilatation of the heart instead of a hypertrophy, which is life-saving. It is only when a dilatation is taking place as indicated by a failure in the strength of the first sound by a wavy impulse, by a dulness extending to the right of the sternum, that drug treatment will be indicated.

As you all know, a patient may live for years with such a condition, all that is necessary being a well-regulated life. To give digitalis because the murmur exists is to cause or hasten harm.

Lesions at the mitral area are of two sorts. There is either a stenosis of the orifice preventing the blood from freely entering the left ventricle from the auricle, or there is some lesion of the valve or orifice which allows the blood to flow back into the auricle instead of onward into the aorta.

In mitral regurgitation of any degree of severity there is hypertrophy of the heart to the left, an accentuated pulmonary second sound, and a systolic murmur of varying pitch conducted into the axilla.

Here, as in all other forms of cardiac disease, the prognosis as to probable length of life and as to the necessity of immediate treatment depends largely upon the character of the first sound and the dilatation of the heart—its size compared with its force. No immediate danger is to be looked for if the heart is regular, the sound good and strong. However, if a murmur which has been loud, begins to disappear, it is often the first danger sign, and calls for immediate interference. I have at present an old lady under treatment for colicolithiasis, who has a mitral regurgitation. When she is in good condition, the murmur is loud and well heard. Immediately she begins to fail, the murmur becomes less audible, until it can scarcely be heard.

In mitral stenosis we have the lesion which, to my mind, is the most difficult to treat in the entire category of cardiac valvular lesions when the heart begins to fail. Here there is hypertrophy of the heart upward and to the right. The right border of heart dulness is to the right border of the sternum or beyond it. The upper border is to the upper border of the third rib or even to the second rib. The left side is but little out of normal line. There may be a marked thrill felt just before the systole, a presystolic thrill. On auscultation there is heard a rough, short, loud murmur just in the region of the apex beat or above it, heard just before the first sound, that is presystolic in time. The first sound is much accentuated, being loud and sharp. The second pulmonary sound is likewise accentuated.

Attention to the peculiar loud accentuated character of the first sound in connection with the peculiar shape of the heart will lead one to suspect a mitral stenosis whether there is a murmur heard or not. And such a diagnosis is quite within the range of possibility, as shown by the following case:

I was called to see a lady suffering with a furious hematemesis. By exclusion and on the grounds of a heart with the right border far too greatly out, the upper border much too high and the peculiar loud valvular first sound which was about the only sign given by auscultation, I made a diagnosis of mitral stenosis as the cause of the bleeding. This was confirmed later by the reestablishment of compensation and the appearance of a loud presystolic murmur.

One reason why this presystolic murmur is so often mistaken for anything else than a presystolic murmur is the *name* presystolic. Certainly the name is confusing. If one will remember, that there are but two sorts of murmurs—systolic and diastolic, and that the murmur of mitral stenosis is *diastolic*, occurring late in diastole, just before the first sound, as distinguished from the murmur of aortic regurgi-

tation which lasts through the whole of diastole, I think there would be less confusion.

The lesion of mitral stenosis is the one which when failure of compensation begins gives rise to the distressing dyspnea—pulmonary edema, hemorrhages from the various mucous membranes, irregular pulse, enlargement of the liver. The seriousness of these symptoms, the bad prognosis when they exist, makes these to me such hopeless cases.

One parting word in regard to the murmurs which exist in this valvular division: A loud, strong murmur, as a rule, means a heart which is well compensated. A murmur loud when the case is first seen and the heart of normal size, with a strong first sound, and then gradually becoming more faint, means a failing heart.

An irregular heart without a murmur, with much increase of its area of dulness, might readily be mistaken for a fatty or fibroid heart. When the action becomes slower and stronger, however, and a murmur makes its appearance, there is every reason to expect a primary valvular lesion. On the other hand, some of the loudest murmurs make their appearance in a heart much dilated as the result of over-strain and still free from valve lesion. Such murmurs invariably disappear as the heart regains its power.

To conclude: The diagnosis of a cardiac lesion must be based upon the size of the heart—upon its rhythm—upon the character of the first sound, in some cases upon the presence or absence of a murmur. A heart may be much damaged and give no murmur. An extremely loud murmur may be present and yet the heart be fully competent.

GENERAL REMARKS ON PAINFUL AFFECTIONS OF THE FEET.*

By FRANK E. PECKHAM, M. D.

of Providence, R. I.,

Orthopedic Surgeon to the Rhode Island Hospital.

The treatment of painful affections of the feet has been pretty thoroughly elaborated especially as regards its mechanical aspect. Good orthopedic shoes can now be obtained with very little difficulty in most cities. The gymnastic exercises, which are particularly beneficial, have been demonstrated; many cases with contracted tendo Achillis can now be markedly improved by gradual stretching with a Shaffer apparatus, and every orthopedic surgeon has his own particular method of mechanically supporting the arch which is so necessary in a large proportion of the cases. In the effort to increase the efficiency of treatment by mechanical means, the general treatment and the treatment of the patient is often overlooked, and I would now emphasize the other measures, which, although mentioned in writings on the subject, are perhaps not given the importance they deserve. There are many cases of flat feet which still continue to be painful, even after all the measures referred to have been faithfully carried out, and these are the cases which demand something in addition to the routine treatment. A foot that has borne weight all day is hot, tender and painful, and all motion limited. A few minutes of

massage is extremely soothing to such a foot. The pain is relieved, the foot is rendered much more flexible, and the gymnastic work can then be done with comfort. If heat is applied just before the massage, the result is even better, and heat alone without massage is of the greatest value just preceding the gymnastic exercises. In hospital cases I have used the hot air oven in almost every painful case with very much benefit. It has also been of great value in cases of contracted Achilles tendons, where gradual stretching was done, the tendon yielding much more and much easier after an hour in the hot air oven. With patients in private practice, to save expense, I have substituted a pail of hot water for the dry heat with very good results. I would say also that the massage in no case has been done by a professional, but either by the patient himself or some member of the household who has been taught to do it. One word regarding gymnastic work. The tip toe exercise is recommended in about every orthopedic work printed, and when in the acute stage of flat foot I attempted this exercise. When the patient goes upward on to the toes and when he is letting himself down again, the pain and tenderness is increased and the pronation aggravated. The exercises which were most beneficial to me and which have given the most satisfaction in practice are those recommended by Dr. Whitman, and they are better done with the patient sitting and the legs resting across a chair or stool. In a varied practice many cases present themselves which refuse to yield to any of the above methods, and then the physician is compelled to tax his resources. Several cases like the following have presented themselves:

CASE I.—A man in middle life, compelled to be on his feet all day and every day, began to have some pain referred to the arch and dorsum of the foot. This became more and more troublesome until he finally sought advice. The patient was a pretty stout man, the arches were somewhat flattened and a slight amount of pronation was present. Motion in flexion and extension was normal but the inversion was slightly limited: A diagnosis of mild flat foot was made and the treatment consisted of orthopedic shoes, supports for the arches, heat to be applied every night, followed immediately by gymnastic work. At first it was thought that there was some improvement, but apparently after getting used to the treatment he could not make out any alleviation of symptoms, and thought if anything they were getting worse. The pain was extending up the leg and was very much worse at night, interfering with his sleep quite a little. Specific disease was denied, but after some time spent in fussing with the mechanical supports, antispecific (mixed) treatment was begun. There was a marked improvement in the first week, and at the end of a month he considered himself much better and discarded the mechanical supports. The orthopedic shoes were discontinued after the single pair and the gymnastic exercises. I am afraid were very much slighted but he continued to take the medicine quite faithfully for about 6 months when he ceased to report. At that time there was no trouble whatever and he considered himself well.

CASE II.—A girl about 14 or 15 years of age, who had been working in the mill very steadily until her feet became so painful that she gave up her work and sought medical advice. There was some flattening of the arch and some slight pronation. The pain was referred to the dorsum and extended down to the 3d and 4th toes. Pressure revealed tenderness along the dorsum of the foot and over the ends of the metatarsals. The pain in this case was much worse at night, interfering with sleep. No history of specific disease was obtainable and none suspected. The patient was sent into the hospital and the treatment was absolute rest in bed, daily hot air baths and gymnastic work. There was very little improvement in the symp-

*Read before the American Orthopedic Association, at Niagara Falls, June, 1901.

toms even after 2 or 3 weeks. As in the other case specific (mixed) treatment was then begun with immediate improvement. She was gotten up with orthopedic shoes applied and exercises continued, but the important thing was the IIg and the KI. She ceased to report after 3 or 4 months, but at that time was apparently all right.

There is another class of cases in which I have only seen three.

CASE III.—A man past 50 years of age was referred to me for hot air treatment on account of a very painful foot. Examination revealed a fairly good arch. Motion in all four directions could be made but it caused some pain. The pain was referred to the dorsum of the foot extending down to the 3d and 4th toes. At times it would extend up the leg. The foot was tender to the touch and he was already wearing very wide shoes so that they would not press on the foot anywhere. Flat foot was excluded but it was impossible to completely exclude metatarsalgia. There was no rheumatic history and specific disease was denied. As he was sent to me to be baked I gave him a hot air bath, which did not seem to do him any particular good. Two or three days later, when he returned, he happened to tell me that he was very thirsty most of the time and drank a great deal of water and consequently passed a great deal of urine. An examination of the urine then and there showed a large amount of sugar present. It is needless to say he did not get a second hot air bath. A year or more later I heard from one of his neighbors that the two toes affected gradually turned black and dropped off.

CASE IV.—A man of about 30 or 35 years of age, a weaver, came to the Out-Patient Department of the Rhode Island Hospital complaining of painful feet. He was of necessity on his feet all day. Examination revealed no especial flattening of the arch and all motions were good. On questioning he acknowledged being thirsty and drinking a great deal of water. The urine showed a large amount of sugar. The patient was referred to the Medical Department and never returned for treatment.

CASE V.—A woman, about 38, consulted me on account of painful feet. The feet were so tender that she was practically unable to wear shoes. There was no particular area to which pain was referred, but rather there was a condition of tenderness all over the foot which was very much aggravated by contact with shoe or stocking. Although the arch was not as high perhaps as the average, yet no especial flattening was made out. Further questioning showed that this patient was drinking large quantities of water, was passing large quantities of urine and was rapidly losing flesh. It was found also that large quantities of sugar were being ingested daily, a tablespoonful being used to sweeten each cup of tea, and many cups taken every day. In many other ways also an enormous amount of sugar was used. Examination of urine showed it to be heavily loaded with sugar. No treatment was directed to the painful feet but the ingestion of sugar was stopped in every possible way, the appropriate remedies prescribed, and a marked improvement in the foot symptoms, as well as other general symptoms, followed almost immediately.

REPORT OF A CASE OF RAYNAUD'S DISEASE.

By BENJAMIN F. LYLE, M.D., and JOHN E. GREIWE, M.D.

of Cincinnati, O.

The following case is reported on account of its rarity, and because a fatal termination is so infrequent as to have rendered its pathological nature only problematical.

E. L., male, white, aged 35 years, married, a native of Austria, lived in this city twelve years, occupation tailor, duration of illness indefinite. Was admitted to Cincinnati Branch Hospital for Consumptives, May 5th, died May 30th, 1900.

Father died of acute rheumatism, mother of puerperal fever. Has two brothers and two sisters, all in good health. Patient had not been sick since childhood. Was intemperate and denied having syphilis. From his friends I learn that his mental equilibrium was unsteady for several years past; previous to that time he was in good mental and physical condition and followed his occupation industriously.

At times, particularly when inspired by the effects of al-

cohol, he would entertain his friends with accounts of his future grandeur when his prospective, though imaginary legacy would arrive. These occasions were frequently followed by a state of moroseness and a desire to withdraw from the company of his friends.

Shortly before his demeanor became noticeable he married. His wife started him in business; but his indifference to work and increasing fondness for drink compelled her in a short time to close the shop. He was then set adrift. Fortunately, he fell in with a Good Samaritan who permitted him to lodge in his shop and furnished him with food. His repugnance to the presence of other people finally became so marked that he could not be persuaded to leave the shop. He never seemed sick, but complained of rheumatism in the legs. This condition interfered some with his ability to walk particularly when the pavements were slippery. His friends also state that he always complained of feeling cold, which sensation was most noticeable in the legs, and he would enjoy heat that would be unsufferable to others. He never had difficulty in walking in the dark, nor did his friends learn of the condition of his feet; although he was not able to walk when admitted to the hospital.

Patient when admitted was weak and anemic and very nervous and irritable. His memory seemed also to be quite defective.

Temperature, 98.6; pulse, 120; respirations, 38.

Tendon reflexes normal.

Examination of lungs showed slight consolidation of both apices.

Urinalysis: Amount, 1000 c. c.

Color, amber, spec. gravity, 1018, reaction, acid; urea, 4.2%; centrifuge examination: Chlorides, 9%; phosphates, 5%; sulphates, 1.2%; albumen, 0; sugar, 0.

The trouble in the feet was first noticed May 2, as an erythema of the toes of the left foot; the next morning this was replaced by cyanosis; but in the evening it again became red and blisters formed on the toes. He complained of no pain except when attempting to walk.

May 4, the tip of the large toe became black. He was admitted to the hospital on May 5. The left foot was then edematous and cyanotic, except the toes which were of a purple color. The anterior half of the right foot was swollen and cyanotic. The toes of the left foot were devoid of sensation. The temperature of the feet, hands, ears and tip of the nose was materially reduced.

On the upper lip was a gangrenous spot about the size of a dime.

May 7, the skin of both feet became more cyanotic, the toes of the left being purple. Blisters had also formed on the toes and soles of both feet.

May 10, discoloration of the feet less noticeable, toes more sensitive, two ulcers were now seen on skin over fibula of left leg each the size of a half dollar. Two gangrenous spots were also found on the scalp each the size of a dime. The fingers of the left hand and elbow had become cyanotic.

From this time until death occurred, the local conditions did not change materially, though the patient seemed very nervous and irritable and at times refused food, making it necessary to employ the stomach tube.

Death was due to exhaustion and edema of the lungs.

Post-mortem examination showed a fibroid condition of the apices of both lungs, edema of the remaining portions, a large quantity of pericardial fluid, and a fatty liver.

The pathological changes in the cord and extremities will be considered by Dr. Greiwe.

The above case was examined by Dr. F. W. Langdon some days before death. He concurred in the diagnosis and could find no trace of any disease of the peripheral nerves or of the spinal cord.

Pathological Report, by Dr. Greiwe.

It is often said, in many obscure affections, that the pathologist and his findings are the court of last resort. In the subject before us, however, we certainly cannot lay claim to any such high position. Owing to the nature of the trouble in most cases, at least so far as our present knowledge goes, the clinician will have to bear the greater burden of

proof. Authentic cases of Raynaud's disease rarely reach the hands of the pathologist. As a matter of fact, we can sum up the cases examined post-mortem on the fingers of one hand. It is equally true that the great majority of cases which have reached the hands of the pathologist up to the present time, in spite of the fact that the clinical diagnosis of Raynaud's disease had been made, post-mortem findings have demonstrated lesions of quite a different nature.

The greatest difficulty in the matter before us, is to say just where to draw the line, clinically and pathologically, between Raynaud's disease and the many other affections which simulate this trouble. Raynaud himself, in 1862, defined it as a disease of the *extremities*, in which there was

- (1) Local syncope.
- (2) Local asphyxia.
- (3) Symmetrical gangrene.

If my interpretation of this definition is correct, we are to look upon such cases as the same disease with only a difference in degree.

Since the time of Raynaud, many important contributions have been added to our knowledge of the clinical manifestations of the disease, but comparatively little has been added to our knowledge of the pathology of this affection. In my opinion one important step, both from a clinical and from a pathological point of view, has been made, viz.: that we can still retain the idea that Raynaud's disease is a symmetrical disease, but that the manifestations are *by no means confined to the extremities*.

In the second place, I believe that the conditions which I have found in this particular instance support the above view. Furthermore, although we have an involvement of the large arteries, I find the essential lesion in the smaller arteries, i. e., in the arterioles.

The appearances of the extremities, and the gangrenous patches on the trunk, have already been described in the clinical report of the case.

I shall confine my attention to the microscopic conditions found in the neighborhood of the gangrenous areas, to the condition of the blood vessels and of the peripheral nerves, and to the lesions found in the spinal cord.

In the specimen taken from the gluteal region in the immediate neighborhood of one of these gangrenous masses, I find a considerable dilatation of the veins, the vessels being crowded with blood. The small arteries are very narrow, and surrounding the arteries, I find a decided small round-celled infiltration. This round-celled infiltration can be clearly traced along the side of the vessel wherever it happens to be cut in its long diameter. In all probability, we are to look upon these changes as those of an inflammatory nature—as an effort of defence and repair—and consequently, we have here nothing of a specific nature. We would naturally expect such a state of affairs, in any area, where a reaction is taking place.

So far as I have been able to discover, the walls of the veins have undergone no change except that of dilatation. There is no change in the internal coat.

As to the small arteries, while some are normal in appearance, others have undergone a change of the intima. There is a distinct proliferation of the endothelial cells. This state of proliferation of the endothelial lining is well marked in many of the smaller arteries. It is best seen in the smaller arteries of the pia-mater of the spinal cord, and even in the smaller arteries of the spinal cord. In no instance have I found a complete obliteration of the lumen of the vessel.

The larger arteries are for the most part normal in appearance. In one instance only, sections of the anterior tibial artery show a beginning localized endarteritis, occupying about one-seventh of the circumference of the artery. In this area I find a distinct proliferation of the endothelium, causing a decided projection into the lumen of the vessel. Beneath the proliferated endothelium there is a decided round celled infiltration in the intima.

Although I find such a change in one of the larger blood vessels, it is not sufficient to interfere seriously with the circulation through the artery.

The peripheral nerves have undergone no change.

The most marked changes in this particular case are those which I find in the spinal cord.

Curiously, the changes are bilateral, symmetrical, and since this condition is, so far as my knowledge goes, found for the first time in the history of a true case of Raynaud's disease, I wish to call special attention to the changes here recorded.

Sections have been made at all levels of the cord. The pia mater of the spinal cord is for the most part normal. Here and there I find a slight thickening and a small round-celled infiltration in the meshes of the pia. The arteries contained within the pia, have undergone pathological changes. The larger vessels show very slight alteration. The smaller vessels (arterioles) show a proliferation of the endothelial cells and a consequent narrowing of the lumen. I find no definite change in the media or in the adventitia, but there seems to be an unusual amount of fibrous tissue immediately surrounding the arteries.

The veins are practically in the same condition of dilatation such as was found in the skin and in the subcutaneous tissue adjacent to one of the gangrenous patches. I find however, that the dilatation of the veins is most marked in the grey matter of the spinal cord, in the lumbar region. I am well aware that similar conditions are frequently found in the cord under otherwise normal circumstances. For this reason, I lay no special weight upon this finding. There is a possibility however, that there is some connection between this rather excessive dilatation and the sclerotic changes in the white substance.

FIGURE 1.—Degeneration in the lateral columns and in the columns of Goll

Excepting this dilatation of the veins in the grey matter surrounding the central canal in the lumbar region, I find that this portion (grey matter) of the cord is normal in appearance throughout. The motor cells in the anterior horns of the cord, are well preserved, they stain well and in no specimen have I been able to discover any deviation from the normal.

In the photographs distinct changes are evident in the white substance of the cord. The sclerosis is bilateral and more or less symmetrical. On the right side of the cord, it is as a rule somewhat more marked and covers a larger area than on the left side.

It will be noticed also, that the changes in the lateral columns are not strictly confined to any of the well-known tracts of fibres, such as we have in a systemic degeneration. Besides the sclerosis of the lateral columns, I find that the posterior columns are also involved, and curiously, in this part of the cord the changes are pretty uniformly confined to the columns of Goll, whereas the columns of Burdach are but very little affected. Indeed, from a macroscopic examination of the stained specimens, one would be led to believe that only the columns of Goll were involved. Microscopically, I notice very slight

changes of a sclerotic character in the columns of Burdach. These changes, however, are not uniform in the last named columns throughout the length of the cord. The anterior columns are not at all affected, and in every specimen, the color with the Pal stain is well brought out. The sclerosis of the lateral columns is found in the lumbar, in the dorsal and in the cervical regions. The most marked alteration is found in the dorsal portion of the cord.

The changes are, I think, well defined in the photographs, and they extend from the periphery of the cord to the horns of the gray matter. Microscopically, thick strands of fibrous tissue can be traced from the pia into the white substance of the cord, compressing and destroying the longitudinal fibres. Wherever the sclerosis is best established, there can also be found slight thickening of the pia, and there, too, I find the condition of endarteritis most marked.

FIGURE 2.—Degeneration in both lateral and both posterior columns.

The photographs which accompany this paper explain the sclerosis found in the spinal cord.

The changes here recorded in the microscopic examination, are certainly interesting in view of the fact that we have always presumed in Raynaud's disease, that the disease is one of nervous origin. Whether the alterations found in the spinal cord in this case are to be looked upon in the nature of cause or effect, is a question which I think can easily be answered. To my own mind, they do not stand in the relation of cause. We know of many instances of more marked sclerosis without any evidence of Raynaud's disease. We cannot explain the trophic lesions of this disease by the changes which I have here recorded. I am inclined to the belief that the changes in the spinal cord are the result of changes in the arteries themselves, and that we have here only another illustration of degeneration resulting from changes in the nutrition of the parts. Just as we may and do have various disturbances resulting from a change in the small arteries of the extremities, so in this case we have changes in an internal organ.

In support of this view, I should like to refer to an undisputed case of Raynaud's disease, reported by Dr. D. Goldschmidt: *Gangrène Symétrique et Sclérodermique* *Revue de Médecine*, 1. VII., 1887.

The case mentioned here was certainly one of Raynaud's disease. The autopsy was conducted by Prof. von Recklinghausen. For a complete history and for a full report of the autopsy, I refer the reader to the original article.

The points of special interest to me are that von Recklinghausen reports a distinct endarteritis of the smaller vessels, and a change (hyaline degeneration) in the walls of the smaller veins. Furthermore, he finds necrosis and sclerosis in different parts of the skin of the extremities, and sclerotic changes in the lungs, i. e., small areas of sclerosis surrounded by hyperemia. These sclerotic areas,

small in their dimensions, were found scattered throughout both lungs. Von Recklinghausen, in his report, calls special attention to these changes in the lungs, and he is inclined to look upon them as evidence of a change similar in character to those which he found in the skin of the extremities.

In view of these facts, I believe that we have every reason to accept the view, that the changes which I report in the spinal cord are of the same kind which von Recklinghausen found in the lungs, and, consequently, they are to be looked upon as the effects of Raynaud's disease, which is a disease of blood vessels.

If such a view can be maintained, we can no longer look upon Raynaud's disease as a disease of the extremities, but rather a disease of the *extremities of arteries*, and that we may, as a consequence, have degenerations, not only in the extremities, but in the *internal organs* as well.

In further support of this view, certain clinical facts which have been developed in recent years in connection with Raynaud's disease, may be cited. Clinically, it is now well known that during the paroxysms which occur in this affection, there is not only a narrowing of the lumen of the larger arteries, but distinct changes in the calibre of the vessels in the *fundus oculi* have repeatedly been observed.

For a complete reference to the literature on this subject, I refer to an exceedingly interesting and instructive article on Raynaud's disease, by Thomas Barlow, in "A System of Medicine," vol. VII., edited by Thomas Clifford Allbutt. From the very limited number of cases which have reached the hands of the pathologists, it would certainly be unwise for us to draw any very general and sweeping conclusions. We certainly have need for further observation in this particular direction.

In view of our knowledge of the clinical manifestations of Raynaud's disease, it is evident that such pathological changes as reported in this case, and in the case so carefully examined by von Recklinghausen, are the exception and not the rule. We know that in the great majority of cases the changes in the circulatory apparatus are paroxysmal in character, brought about by some temporary condition, which allows of changes in the peripheral circulation.

The influence of great excitement, of anger, and, furthermore, the beneficial effect of hypnotism, are well illustrated in an article by Dr. Paul Tesdorf:

Beitrag zur Lehre von der Symmetrischen Gangrène.

Such cases are obviously more frequent in literature than the case which has here been presented.

I am led to the conclusion, therefore, that we have, in all probability, two classes of cases:

(1) Those cases in which the exciting cause acts temporarily, and in which, with the cessation of the cause, the symptoms likewise disappear.

(2) Those cases in which the cause (as yet of an unknown character) acts upon the peripheral vessels and causes changes in the calibre of the vessels, by a proliferation of the endothelium.

If any conclusion seems justifiable, it is this, that Raynaud's disease may show lesions, not only of the extremities, but serious changes may occur in the internal organs as well.

Cyto-diagnosis.—The discovery of the different cellular elements in the cerebro-spinal fluid obtained by lumbar puncture has lately become a means of diagnosing various nervous diseases. Numerous reports upon this method of cyto-diagnosis have been made before the Medical Society of the Paris Hospitals. The first communications were made October 17, 1900, by Widal and his assistants, Sicard and Ravaut. Monod (*Bulletins et Memoires de la Societe Medicale des Hôpitaux de Paris*, 1901, No. 2) examined the cerebro-spinal fluid of 50 different nervous patients, finding leukocytosis in locomotor ataxia and general paralysis. No cellular elements were found in hemiplegia, alcoholism, peripheral neuritis, or hysteria. Widal, Sicard and Ravaut (*Ibid*, 1901, No. 2) found that the leukocytes seen in tuberculous meningitis were mainly lymphocytes; while in epidemic cerebro-spinal meningitis only polynuclear leukocytes occurred. This was confirmed by Chauffard (*Ibid*, 1901, No. 11) and Boinet and Raybaud (*Ibid*, 1901, No. 19). In general paralysis and tabes they found abundant lymphocytes. They also failed to find cellular elements in typhoid fever, paralysis agitans, chronic chorea, delirium tremens, progressive muscular atrophy or hemiplegia. Sicard and Monod (*Ibid*, 1901, No. 2) found lymphocytes only in syphilitic meningomyelitis. Widal (*Ibid*, 1901, No. 2) also found lymphocytes mainly in meningomyelitis, both when syphilitic and when due to typhoid fever. Nageotte (*Ibid*, 1901, No. 3) believes that in syphilitic meningomyelitis mononuclear leukocytes predominate in the cerebro-spinal fluid, while in non-specific cases, the majority of the cellular elements seen are polynuclear leukocytes. Labbé and Castaigne (*Ibid*, 1901, No. 12) discovered that the polynuclear leukocytes seen in epidemic cerebro-spinal meningitis disappear as the patient recovers. Sicard and Brécy (*Ibid*, 1901, No. 13) report a case of "walking" epidemic cerebro-spinal meningitis, in which polynuclear leukocytes were found during the very acute stage, mononuclear lymphocytes during the sub-acute chronic stage. In this case the osmotic tension rose from 0.54 early in the disease to 0.60 near recovery. Babinski and Charpentier (*Ibid*,

1901, No. 17) found marked lymphocytosis in the cerebro-spinal fluid in tabes of specific origin. Babinski and Nageotte (*Ibid*, 1901, No. 18) report the results of 120 cases of different nervous diseases examined. A "walking" case of epidemic cerebro-spinal meningitis was diagnosed from the polynuclear leukocytes found by lumbar puncture. Lymphocytosis was found in tabes and general paralysis. Lymphocytosis seen in the cerebro-spinal fluid from a woman whose condition had been diagnosed alcoholic polynuritis, showed that the true condition might be tabes. The cerebro-spinal fluid was normal in hysteria, neurasthenia, brain tumor, hemiplegia, paraplegia, chorea, epilepsy, etc. They conclude that a pronounced lymphocytosis is always a sign of diffuse syphilitic lesions, and is found early. Joffroy (*Ibid*, 1901, No. 18) insists upon frequent puncture, as the conditions found change rapidly. Dupré and Devaux (*Ibid*, 1901, No. 20) also found lymphocytosis in general paralysis, as did Siglas, Nageotte and Joffroy (*Ibid*, 1901, No. 20). The results in senile dementia and melancholia were negative. They believe that the cellular elements found in the cerebro-spinal fluid show the existence and the intensity of meningeal reaction. Widal (*Ibid*, 1901, No. 20) considers lymphocytosis a sign of a chronic lesion of the meninges. It is not present with meningismus. Souques and Quiserne (*Ibid*, 1901, No. 22) report a fatal case of tuberculous meningitis in which lumbar punctures showed a continually increasing number of lymphocytes, and low osmotic tension, first 0.51, later 0.55. Cerebro-spinal fluid injected into rabbits caused tuberculosis. The diagnosis was made from the examination of the cerebro-spinal fluid. Bourey (*Ibid*, 1901, No. 22) and Faisans (*Ibid*, 1901, No. 23) reported similar cases, settled by cyto-diagnosis. Laignel-Lavastine (*Ibid*, 1901, No. 22) found that leukocytosis exists early in general paralysis; that when cachexia develops, the number of leukocytes varies; that three-quarters of the leukocytes found are lymphocytes; and that when many polynuclear leukocytes are found with lymphocytosis, in tuberculous meningitis, meningeal suppuration has occurred. He also found that, while lumbar injections of cocain, for sciatica or the gastric crises of tabes,

may produce temporary amelioration, they also cause leukocytosis, from the meningeal irritation produced by the puncture. Achard and Lanbry (*Ibid*, 1901, No. 23) report a case of supposed tuberculous meningitis, in the cerebro-spinal fluid of which a moderate lymphocytosis occurred. Autopsy revealed a cerebellar tumor, however. They believe that for an exact diagnosis, the number of leukocytes must always be counted. Cyto-diagnosis has also been used in herpes zoster. Brissaud and Sicard (*Ibid*, 1901, No. 10) found many mononuclear leukocytes and decreased osmotic tension. The French physicians are still at work collecting statistics which they hope will lead to yet more important general conclusions.

What Koch Really Said.—There seems to be some confusion, both in the professional and in the lay mind, as to what Professor Koch intended to teach in his recent address. A restatement of his position is not undesirable—especially with reference to possible interpretations of his remarks. Such a restatement is admirably made, with running criticisms, in a recent circular issued by Veterinary Surgeon Gresswell, who is Chairman of the Sanitary Committee of the National Live Stock Association. We abstract his main conclusions.

Dr. Koch failed in nineteen cases to convey human tuberculosis to bovines, but in no instance failed to convey bovine tuberculosis to bovines in a similar manner. He had not attempted, for obvious reasons, to convey either bovine or human tuberculosis to human subjects. There is not on record a case of experimental inoculation of a human being with tuberculosis, either bovine or human (although, as Dr. Leonard Pearson pointed out recently in this *Journal*, there have been a few accidental cases of inoculation from cattle). Although there is very suspicious evidence of the conveyance of both human and bovine tuberculosis to man, there is no absolute proof of one more than the other. In other words, the proof of contagion from man to man is no better than from bovine to man. It therefore seems that the only *positive* result obtained by Koch was that bovine tuberculosis is communicable to bovines. This seems rather a narrow ground upon which to build a great superstructure of doctrine and practice. Moreover, as Surgeon Gresswell points out, bovine tuberculosis is communicable to other animals, just as is human tuberculosis. The dog, sheep, cat and monkey have been inoculated with the bovine bacillus.

It is thus seen that Koch advances no positive proof that bovine tuberculosis is not communicable to man. He simply infers that as bovines cannot be infected with the human tubercle bacillus, therefore the converse is true, i.e., that man cannot be infected

from cattle. His inference that bovine tuberculosis is not communicable to man because so few cases of direct intestinal infection occur, is a weak one when it is recalled that intestinal disorders in children may be caused by the toxins in milk as well as by the bacilli themselves. It is true, however, as veterinarians have observed, that calves suckled by tuberculous cows are prone to die of mesenteric tuberculosis. The bovine bacillus is well known to be more virulent than the human form, and this fact may account for the greater facility of inoculating with it. It is nevertheless true that in parasitic life those parasites inhabiting one species may be unable to perpetuate themselves in animals of a different species.

It is noteworthy that this circular is issued by an official of the National Live Stock Association, and is an appeal for caution against the hasty or premature adoption of Koch's views.

In conclusion, we desire to point out as our own contribution to this discussion that Koch's experiments on swine seem to prove mainly that bovine tuberculosis is more virulent than human tuberculosis for these animals. This is only additional proof that the tubercle bacillus, taken from the cow, is the most virulent of all forms, and therefore most to be dreaded. May not this apply in the case of man as well as in the case of swine?

The Open-Air Treatment of Phthisis.—The danger of adopting "fads" in therapeutics is never an imaginary one, and tuberculosis is especially exposed at present to this risk. The open-air treatment, however, is so well vouched for, and is so in accord with reason and experience, that we may really believe it constitutes an advance in therapy. Dr. Hector Mackenzie, of London, is one of the firmest advocates of this plan, and has just published his views in the July number of the *Practitioner*. Dr. Mackenzie argues that an open-air treatment should be what its name implies—consequently he advises that tuberculous patients be kept in the open air during sunshine and storm, during heat and cold, during day and night. His most striking cases were kept on an open balcony at St. Thomas Hospital for months. And all this, it is to be remembered, was done during the changes and inclemencies of a London autumn and winter. A patient, for instance, with a tuberculous cavity in the right upper lobe, with hemoptysis, fever and rapid emaciation (a patient, in other words, who was in a rapid decline), was put out of doors in his bed, and kept there constantly night and day for six months. In a month's time his temperature became afebrile, his appetite returned, his sputum diminished, hemoptysis ceased, and his weight began to increase. He gradually gained twenty-eight pounds and acquired a com-

plexion of red and tan. At the end of the six months he left the hospital restored to health. This case is almost too favorable to be accepted as a criterion. It inspires a hope that is too optimistic. The reader naturally fears that only a few cases can do so well. But Dr. Mackenzie supports his position so plausibly that he is likely to make converts, and we trust other as favorable cases will soon be reported, especially from this country.

The requisites for this treatment are simple in the extreme. The patient is kept warm in bed, not only with blankets, but with such other aids, if needed, as hot-water bags, gloves and a woolen cap. He is fed almost to excess. This feeding is especially a feature of the Nordrach treatment in Germany, where the repasts are on a Gargantuan scale. The treatment, in fact, may fail if the patient is not literally bullied into eating heroically. Moreover, the patient is isolated and not allowed to talk except to doctors and nurses.

As for the patients themselves, they are said to like the treatment and to enter heartily into the spirit of it. Here is where suggestive therapeutics comes in. Dr. Mander Smyth, himself a victim, tells how at Nordrach he would awaken at night to find an inch of snow on his coverlid. The rationale of the treatment is plain: fresh air is stimulating, appetizing, roborant, soporific and alterative. What more can be asked of one agent? At the Mill Road Infirmary, in Liverpool, 824 cases received open-air treatment, and of these cases 232 patients were so much improved as to be able to return home and resume work, and 83 patients were completely cured. And this was in the very center of Liverpool, without a blade of grass in sight.

Tuberculosis of the Conjunctiva.—The healthy conjunctiva absorbs infectious materials into the economy with difficulty. As an illustration of this may be taken diphtheritic conjunctivitis, which frequently exists without systemic involvement, unless there follows a transportation of the infection through the lachrymo-nasal passages. When tuberculosis of the conjunctiva exists, it is sometimes found that one lid is the seat of a typical tuberculous process, while the other lid may not only remain exempt in spite of the mutual contact, but may become the seat of a chronic hyperplasia without a demonstrable tubercular lesion. Such a case was not long ago reported by Ulthoff (*Berliner klin. Wochenschrift*, Jahr. 37, No. 50, p. 1145), in which microscopical examination showed with certainty the presence of tuberculosis of the lower lid, while the upper lid was in a condition of chronic hyperplasia, without any tuberculous changes. This presents the interesting pathological problem, what agent, directly or indirectly depend-

ent upon the tuberculous area produces this hyperplasia? Is it the specific action of the toxins, is it the long-continued irritation of the toxins without any specific toxicological action, or does a mixed infection cause this condition? That changes, which are probably not tuberculous, may exist in tissues adjacent to tuberculous areas, is illustrated in meningitis, pleurisy, and arthritis. Valude's careful experiments on animals seem to show that the healthy conjunctiva is one of the most resistant portals for the entrance of the tubercle bacillus.

Cysts of the Omentum.—The diagnosis of abdominal tumors is one of the most difficult of all problems in medicine. It may be a question whether any man who practically discovers a new kind of abdominal tumor, or at least studies a case of this nature so carefully that he presents it in a new and conspicuous light to the medical profession, should be regarded as altogether our benefactor. Dr. Abraham Jacobi has certainly, however, been a benefactor to medical science in many ways, and his description of a cyst of the omentum, read before the Association of American Physicians, and subsequently published in the *New York Medical Journal*, is a valuable contribution to current medical literature. It calls the attention of many of us clearly to the fact that such a tumor may exist, and may render the differential diagnosis more difficult.

Cysts of the omentum are, of course, rare, but this fact is small consolation to the physician to whom is presented the task of determining the nature of some intra-abdominal growth, that has baffled, perhaps, a number of his colleagues. For who can tell what moment the rarest of rare cases may not be before him? Moreover, a correct diagnosis is of the utmost importance, because the treatment of this cyst is comparatively simple and successful. In the present instance (the patient was a girl 7 years of age), after repeated tapping, laparotomy was performed, and a large multilocular cyst of the great omentum was readily removed entire, with perfect recovery. The diagnosis was not made until the operation, but Jacobi implies, although he does not definitely state, that in cases of tumor in the abdomen from which fluid can be removed by paracentesis, and which rapidly refills, when there is no alteration in the temperature, either from the absorption of fluid, or from tapping, a certain degree of suspicion is justifiable.

Dr. Jacobi is to be warmly congratulated or having had the opportunity of observing this extraordinary case; and, after all, we think it just as well that the profession should be bothered a little more by having its attention called to this form of tumor.

The Resistance of the Larvae of Mosquitoes to Intense Cold.—The ability of the very lowest vegetable forms of life, such as the various bacteria, to resist intense cold has been proven in many instances. The subject, as can readily be seen, has direct practical importance. Cold seems to be a very uncertain agent indeed for the destruction of many of the pathogenic bacteria, although it may suspend their activities—as in the case of yellow fever (if the parasites of this disease are really bacteria). It now seems that not only these lowly vegetable forms, but also some lowly insect organisms (which are, however, high in the biological scale above bacteria) can successfully resist a very low freezing temperature. This has recently been discovered in an unexpected way in the case of the larvae of the mosquito; and as these insects are now of extreme significance in pathology, this whole subject has direct interest for medical men.

Dr. J. B. Smith, State Entomologist of New Jersey, relates, in the *Entomological News*, that in the leaves of the pitcher plant (*Sarracenia purpurea*), growing in swamps and bogs in that State, the larvae, or "wrigglers," of mosquitoes have been found in abundance. Late in November, 1900, Dr. Smith found some of these larvae still alive in these plants, and concluded that they must soon perish so late in the season, as larval hibernation of the mosquito was unknown to him. In the following January, after a bitter cold spell, during which the thermometer registered 2° below zero, Mr. J. T. Brakeley procured some of the leaves of these pitcher plants, and removing the solid lump of ice from the interior of each one, and holding it to the light, saw that numerous larvae were imbedded in it. These he proceeded to thaw out, and found to his surprise that they all revived and resumed their active functions of moving, feeding, etc., as soon as they were liberated from the ice. He sent several jars, containing these larvae, to Dr. Smith, who watched them during several months, and has recorded his observations in a paper of great interest.

Dr. Smith found that these larvae, thus thawed out and kept indoors during the winter months, were very slow to develop into the pupal stage. This development usually takes place in a very few days in normal conditions, but Dr. Smith did not observe it in his larvae for many weeks. In the meantime, however, these wrigglers continued active. Finally, in March, by maintaining a constant high temperature in the jars (80° to 90°), Dr. Smith forced some of the larvae to develop, and so obtained a few perfect insects of the variety of Jersey mosquito known as *Culex pungens*.

All this is of extreme interest—not more to the entomologist than to the physician. The ways of

mosquitoes are of great importance to science. Dr. Smith calls attention to the now rather well-known fact that in the Arctic regions mosquitoes are found in great clouds during the short summer, and make life unbearable to man and beast. It would seem probable that these Arctic mosquitoes hibernate in the ice in the larval stage. None of the larvae of the *Anopheles* were observed among Dr. Smith's specimens, but it seems to us reasonable to suppose that the larvae of these malarial mosquitoes may be equally resistant to cold. Some of Dr. Smith's specimens were the larvae of *Aedes*, a smaller genus of the mosquito family.

The Registration of Stillbirths.—Now and again the attention of the profession is called to some irregularity in the registration of infants that are stillborn. This is especially true of England and the continent, although it cannot be claimed that we in this country have by any means arrived at a degree of perfection in this respect. It is a matter of congratulation, however, that in this city within recent years it has become compulsory not only to make a return of all stillborn children, but that each blank must be made with a special name, thereby rendering still more accurate the vital statistics of the community. To those who will give the matter serious attention it will be quite obvious that more important aspects are concerned than would at first sight appear. It is not merely for the purpose of perfecting the country's vital statistics, important as this undoubtedly is, that careful registration is imperative, but there is a medico-legal side of the question that deeply concerns the welfare of the country. Under lax laws and regulations the nefarious craft of the criminal abortionist and incompetent and conscienceless midwife is so protected that crime becomes rampant, and open defiance of moral legislation results. In England, as was testified to recently in an editorial note in the *British Medical Journal*, the matter has advanced to such a degree of laxity that children who die within 24 hours of birth are constantly received in the cemeteries and buried as "stillborn." This is undoubtedly a boon to the indigent among the people who are thereby spared the expense of a funeral service, but the dangers of such a course are evident. Not only may the products of criminal interference thereby be legally (?) disposed of, but infanticide is actually fostered and the way made plain and easy for evasion of an important safeguard of the stability of the people. There is already enough of ill resulting from the countenancing of incompetent midwives without magnifying their evil effects by opening to them a safe way for increasing their ill-gotten gains through illegal con-

cealment of births and deaths. After the period of fetal viability has been reached, legislation that would make compulsory under penalty of fine or imprisonment or both the registration of a premature birth is most desirable. Such children, designated by a Christian name and the surname of their father, should receive legal interment, and the records of births and deaths thereby be rendered so much the more complete for the given community. It would be gratifying and, we believe, beneficial in results, both statistically and morally, if some method could be devised whereby an accurate registration of all ovular and embryonic births prior to the period of viability could be obtained or even made compulsory. In order to arrive at some satisfactory and accurate records of fecundity, the many prematurely ended pregnancies must be taken into consideration.

Simple Acholuric Jaundice.—Gilbert and Lereboullet, who have examined hundreds of cases of simple acholuric jaundice, include under this head all cases of jaundice with acholuria, or with minute, intermittent choloria. By the most exact tests only a trace of the biliary pigment is found, or none at all. While the acholuria is scientifically not absolute, it is, clinically. In all these cases a chronic obliterating angiocholitis occurs. They separate these cases into two types, subicteric cholemia, with marked jaundice, which is the most common form, and anicteric cholemia, with little or no jaundice. The biliary pigment is always found in the blood serum, even though jaundice has disappeared. The condition often exists in many members of one family. From the many examinations made, there seems to be no disease of the liver which is not at some time accompanied by cholemia. Hemorrhages are seen all over the body. The dyspeptic form of the disease is the most frequent, and occurs generally in the family whose history shows many cases of liver disease. There are pain, in the epigastrium, after eating; dilatation of the stomach; and slight hyperchlorhydria. The jaundice may be absent; it may only affect the face; the body may be yellow; and finally the eye-lids will show a deep icterus. Salkowski's method will reveal bile pigment in the blood serum; and this will be absent from the urine. Slight melancholia may exist, gastrointestinal hemorrhage, urticaria, pruritus, rheumatic pains, etc. Occasionally intermittent fever is noted, and a slow pulse is the rule. Rarely the dyspepsia exists first, generally the two appear together, or the dyspepsia follows the jaundice. The diagnosis is not difficult. The dyspepsia is secondary. A diet of skimmed milk should be ordered first for two weeks, then two weeks of soft food, and then only can solid food be given. Bismuth, prepared chalk, etc., will do good. (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, May 23, 1901, No. 17). In the discussion which followed, Chauffard said that he considered those cases in which some slight biliary pigment was found in the urine hypocholeoric, not acholuric. [M. O.]

The Abolition of the Pupillary Reflex to Light a Sure Sign of Syphilis.—Babinski and Charpentier report four cases of syphilis in all of whom the pupils showed the Argyll-Robertson reaction, failure to react to light. They believe that not only is this a certain sign of syphilis, hereditary or acquired, but that it also shows, even in the absence of all other symptoms, the approach of locomotor ataxia, general paralysis, or confirmed cerebrospinal syphilis. The time to elapse before the other symptoms appear is variable. Other observers reported cases which showed that the Argyll-Robertson pupil was often followed by the appearance of more severe syphilitic manifestations. (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, May 23, 1901, No. 17). [M. O.]

Reviews.

A Treatise on Orthopedic Surgery.—By Royal Whitman, M. D. Lea Bros. & Co., Philadelphia and New York. 1901.

The author, in the preface, says that this work is designed for students and practitioners of medicine, but hopes it may prove of interest to those who confine their work to the specialty of orthopedic surgery. The work is based upon clinical experience and investigation, and contains numerous statistical tables, both original and quoted from other sources. It contains large numbers of good original illustrations, mostly photographs of patients, illustrating with great clearness the various stages and types of deformity. Much attention is paid to the etiology and anatomy of deformities. Thus the discussion of the deformities of the foot is prefaced by a discussion of the anatomy of the foot and its arches, its functions, and from this the effect of improper posture and the various pathological changes leading to deformity and disability are demonstrated. Symptomatology and treatment are dealt with with equal thoroughness, the latest contributions to mechanical and operative treatment being fully considered. Among the special articles it might be mentioned that the author is decidedly conservative in his discussion of the treatment of spinal abscess. The endorsement of the benefits of the plaster-of-paris jacket in the treatment of Pott's disease, especially in conjunction with Bradford's frame, impresses us favorably, although the recommendation of the old jury mast with its inefficient extension and poor fixation in the treatment of high spinal caries is disappointing. While he does not condemn Calot's operation of forcible correction of kyphosis, he leaves the final judgement to be given later. Goldwaite's method of gradual correction receives its just praise. The chapter on sacro-iliac disease is too brief considering its importance. The discussion of the relative merits of the traction as contrasted with the fixation splint in the treatment of coxalgia, the so-called American and English methods, is very good and furnishes many data not usually obtainable in text books. The author while admitting that excision is seldom needed in cases of coxalgia properly treated, also believes that in hospital cases it is often postponed to too late a period both as a life saving and function preserving operation. The articles upon congenital dislocation of the hip, and coxa vara, are beautifully illustrated with very instructive photographs and skiagraphs. His views on congenital dislocation are in accord with the most recent ones on this subject: open operating being recommended when the Lorenz bloodless operation fails. There are a number of subjects discussed which are only indirectly orthopedic in nature, and there might be mentioned injuries of the epiphyses, infantile scurvy, fragilitas ossium, acromegaly, and other trophic or neuropathic bone diseases, which subjects are, however, discussed only superficially and briefly. The book approaches near the standard of the ideal orthopedic surgery, and appears to us to be the most up to date book upon this subject in the English language. [H. R. W.]

Compendium der Physiologie des Menschen.—Zweite verbesserte und vermehrte Auflage. Von Dr. Paul Schultz. Verlag von S. Karger, Berlin. 1901.

A compend of the essential facts of the different branches of medical science as taught in most medical schools seems to be necessary to the present day student. The various text-books are so large, the time for reading so limited, that the student is compelled from necessity to have at hand a small book to which he can refer and obtain without difficulty the facts he especially desires. It would appear that the compend is a necessary volume, even in Germany. The present volume is one of a series, some of which are intended for students during their attendance on lectures, others for preparation for state examinations. In the preface the author states that brevity and clearness in the presentation of the facts recognized at the time should be the essential characteristics of a

compend. An examination of the various chapters will convince one that the author has succeeded in accomplishing this. All the essential facts of the subjects are presented in a clear, compact form, easy of apprehension by the busy student. To those students who read German this volume will be a valuable companion for reference and for preparation for examination. [A. P. B.]

Annual Report of the Smithsonian Institution for the year ending June 30, 1899. Government Printing Office, 1901.

This is a very excellent publication, and one to which we can refer with pride, because it is published by our own Government for the purpose of facilitating the knowledge of scientific progress. The contents consist of 140 pages, devoted to reports, expenditures, etc., and an appendix of more than 500 pages consisting of a "miscellaneous selection of papers (some of them original) embracing a considerable range of scientific investigation and discussion." Among the most interesting of these are the papers on Radio-Active Substances, by H. C. Bolton; the "People of the Philippines," by Rudolf Virchow, "A List of Native Tribes of the Philippines, and of the Languages Spoken by Them," by Blumentritt, and an article on "Von Zeppelin's Dirigible Air Ship." The latter is a reprint. But many of the other papers are of even more scientific importance. We note with regret that no bison were born in the Zoological Park during the year 1899. It seems as though this magnificent animal were doomed to extinction. [J. S.]

Transactions of the Southern Surgical and Gynecological Association, Vol. XIII. Thirteenth Session, held at Atlanta, Ga., Nov. 13-15, 1900. 436 pages. Published by the Association, 1901.

The thirteenth volume of these transactions is rich in valuable and suggestive papers. Among the topics are: Medullary Narcosis, by W. L. Rodman, M. D.; Excision of the External Carotid Artery for Inoperable Sarcoma of the Face, by Wm. Perrin Nicholson, M. D.; Resection of the Rectum per Vaginum, by John B. Murphy, M. D.; The Surgery of the Gasserian Ganglion, by Wm. Neff, M. D., and Resection of the Cervical Sympathetic for Glaucoma, by Howard J. Williams, M. D. Papers are also presented by such well known writers as J. McF. Gaston, Jr., W. P. Manton, Geo. J. Engelmann, A. Morgan Cartledge, and George Henry Noble. The book is full of valuable information and is a worthy successor to the volumes that have preceded. [W. A. N. D.]

Transactions of the Associated Physicians of Long Island, January 1900 to June 1901. Vol II.

This neatly printed, artistically gotten up and tastefully illustrated volume contains papers to the number of eight, read at the second and third annual meetings of the Association in January 1900 and 1901, and the seventh and eighth regular meetings of June and October, 1900, together with a record of the executive transactions, the revised Constitution and an accurate list of members. An attractive title-page and a device for an Association seal are originally designed by members. [A. A. E.]

Transactions of the American Pediatric Society. Twelfth Session, held at Washington, D. C., May 1, 2 and 3, 1900. Edited by Walter Lester Carr, M. D., Vol. XII. Reprinted from the Archives of Pediatrics.

Except for convenience of preservation and reference there seems to be no special need for the republication of the 23 interesting and valuable essays contained in this volume, as they have already been once published. Nothing but praise can be accorded the papers themselves, which represent the labors of men actively and intelligently engaged in the study of the subjects discussed. [A. A. E.]

Correspondence.

VACCINATION REQUIRES ASEPSIS.

By FREDERICK GRIFFITH, M. D., of New York.

Surgeon to Bellevue Dispensary; Fellow of the New York Academy of Medicine.

To the Editor of the Philadelphia Medical Journal:

It is sounding the old theme, when I say that attention to details is most necessary to highest success in medicine and that the neglect to put in practice the commonest principles of present day medical science is the cause far more often of failure than foolhardy attempts at unreasonable procedures.

The neglect of these principles has brought the following cases before me during the past month.

By requiring children to show well-marked vaccination scars before being permitted enrollment in the public schools of the city the authorities seek to avoid one channel of disseminating smallpox; but every year there is such an increase in the number of children born, besides those under school age that advantage is taken of every opportunity to vaccinate, as in one of the instances in this report where a child taken sick with scarlet fever gave rise to a call from a district health officer and the vaccination of ten remaining children resident in the large double tenement occupied with their parents.

The first case was that of a little girl aged three years who was one of ten to be vaccinated at the same time.

She had been vaccinated, for the first time, three weeks before, upon the left arm at the insertion of the deltoid muscle.

Over an area of two and one half inches wide by four inches long were scattered pustules, some umbilicated, confluent and distinct with broad inflammatory areas surrounding. The contents was a creamy pus.

In the centre of the area was a circular, brown discoloration the size of a silver dollar, bounded by a whitish ring.

The discoloration turned the color of and looked much like a piece of old, tanned leather, as it sloughed away during the course of the following week.

The pustules broke down the surrounding cellular tissue leaving a suppurating area which healed slowly by granulation.

There was no involvement of the axillary glands nor was there any constitutional reaction.

There was evidently no discomfort or pain felt as the child never voiced complaint, excepting during the removal of early dressings, from fear. The treatment consisted in washing with hydrogen di-oxide and the application of narrow strips of rubber tissue, laid on shingling fashion to allow the oozing to penetrate to a light, dry gauze dressing.

Of the other two cases; one was in a child of two years; without any glandular involvement an abscess formed upon the back of the arm, three inches from the site of vaccination.

Opening the abscess cavity I curetted one half an ounce of green streaked pus and slough.

After washing out the cavity with hydrogen di-oxide I drained with a small loose twist of rubber tissue, applying light gauze to complete the dressing.

The third case was one of less degree of infection and occurred in a second child of the ten, vaccinated.

To lessen the danger from infection to a minimum, district health officers should order that children to be vaccinated, be brought at a specified time to a nearby surgical dispensary where the part to be treated may be made as aseptic as for an operation. No difficulty would arise from failure of co-operation upon the part of the attending surgeon if the matter be set before him, as by a little interest at this time he can save the child the dangers from pus infection and himself the subsequent care, the inspector taking no further notice of the case.

The value of hydrogen di-oxide and the use of rubber tissue in these as well as all other suppurating wounds cannot be overestimated.

The hydrogen di-oxide used in full strength or dilute, according to the pain caused, cleans the wound; the rubber tissue, in strips acting to reduce the irritation of the dressing of absorbant gauze.

THE PROBLEM OF ANESTHESIA.

By S. OILMOND GOLDAN, of New York

To the Editor of the Philadelphia Medical Journal:

In the Philadelphia Medical Journal, July 13, 1901, you describe editorially a new method of anesthetization by Braun.

This is not a new method at all but simply an elaboration of the Junker method of administering chloroform, and introduced by Tyrrell London (*Trans. Soc. of Anaest.*, 1898, Vol. 1, p. 1) as the double bottle method. The method like many others is a most useful one in experienced hands but should not be advocated for occasional administrators or hospital internes as distracting attention from the patient to the apparatus. "The problem of anesthesia will not stay down" until it is solved, and that properly. You say ether is not an ideal anesthetic; neither is nitrous oxide or chloroform, but when the profession realize each and all of these anesthetics have their particular and definite indications and adaptability, and correct methods are employed in selecting and administering each of them, the subject of anesthesia will near solution, as near at least as such a subject can.

In spite of the fact that the introduction of anesthetics was one of the two great factors by which surgery has advanced to its present state, anesthetization is practically where it was fifty years ago. To the minds of most, anesthetization begins and ends with a towel and paper inhaler and a can of ether. Is there then, any surprise that "the subject will not stay down." It can further be said that the symptoms mentioned in your editorial as usually those developed during etherization are owing to its improper and not proper administration—they are properly the exception and not the rule. Why blame the anesthetic?

To use either one of our three anesthetics to the entire exclusion of the others would increase the mortality greatly both immediate and remote; to use each and all of them in their proper place would likewise reduce mortality. When, oh when, will the profession realize this fact? Is it right to give chloroform for insignificant operations as tooth extraction, abscesses, etc., and have the patient die, when nitrous oxide would have answered?

It is safe to say there are exceedingly few in this country who have a thorough practical experience in the administration of our three anesthetics, gas; ether; chloroform.

Further you say chloroform has few of the disadvantages of ether but has a fatal effect of frequently causing cardiac or respiratory paralysis—the probable truth of the matter is, it is most frequently vasomotor paralysis and only secondarily cardiac and respiratory—due to what—chloroform? No; but overdosage due to improper administration. The safest conceivable method of administering anesthetics would be unsafe in inexperienced hands. I have in more instances than one said this, but it seems to be most frequently lost sight of.

The principles governing the safe administration of chloroform are extremely simple—how many know them? Probably not one in a hundred, and if known rarely followed. So, why blame the anesthetic? Always an interesting question, why the fatalities early in chloroformization?—not infrequently it is said to be fright—but many patients are frightened during etherization and very rarely do any die. Fright is always accompanied by more or less holding the breath and more or less though not necessarily visible asphyxia—when breathing does commence so large a quantity of the anesthetic is taken in as to cause sudden death—not fright, but overdosage, though the amount of the anesthetic may be amazingly small. In connection with this it is simply necessary to remember that but 24 minims of chloroform if given in a certain manner, produce complete anesthesia.

Ought this not to teach that chloroform should not be given to a frightened patient, and, if necessary, ether, or gas and ether, should precede it—that to give chloroform to a struggling and oftentimes forcibly restrained patient is the very worst possible thing to do—it is simply trifling with life.

An absolute essential for chloroformization is normal regular breathing. Enter most clinics and note the manner in which this anesthetic is administered and say whether it is surprising that fatalities occur. Rather is it not surprising that mortality is not even greater than it is?

OIL OF PENNYROYAL AS A REMEDY AGAINST MOSQUITOES.

By V. H. McKNIGHT, M. D., of Lima, Ohio.

To the Editor of the Philadelphia Medical Journal:

Now that the annihilation of the mosquito seems to be fairly resolved upon, is it generally known that the Oil of Pennyroyal is antagonistic to them, that they will avoid sleeping people who have it about the bed?

That seems to be a fact, and if the fact can be better proven, can it be utilized in the war against the mosquito?

Broncho-pneumonia with Pulmonary Sclerosis.—Evaristo Lafforgue, in *Medicine Moderne*, (1901, No. 16), describes a case of broncho-pneumonia in a man of 60, who had always taken too much absinthe. He was greatly depressed, seemed very old, and talked unintelligibly. He felt very weak, with pain at the base of the chest. He coughed much, with dark, mucopurulent expectoration. The dyspnea with the cough was intense. Dulness, with subcrepitant and crepitant rales, was found over the left base posteriorly. Over the rest of the chest were rales of all kinds. Anteriorly emphysema was noted. Arteriosclerosis was marked, and the heart hypertrophied. He was constipated, and the urine contained albumin. A week later he died, asphyxiated. At the autopsy the lungs showed localized emphysema with small hemorrhages and abscesses, marked sclerosis, and disseminated broncho-pneumonia. The heart was hypertrophied, with myocarditis. The kidneys and liver were sclerotic and atrophic. Pneumococci and influenza bacilli were found microscopically. The presence of the pulmonary sclerosis gave the broncho-pneumonia a special character. It localized the areas, causing the infection to develop and to spread. It also caused suppuration and necrosis in these closed areas, with localized hemorrhages and emphysema. As it gradually destroyed all the air spaces, dyspnea and asphyxia followed. [M. O.]

Pneumothorax Treated by Pleurotomy.—At a recent meeting of the Medical Society of the Paris hospitals (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, 1901, No. 1.), Dr. L. Galliard reported the case of an Italian woman aged 25, who had been coughing for over two weeks. On admission to the hospital, dyspnea and cyanosis were extreme, and there was slight fetid, mucopurulent expectoration. Examination showed partial right-sided pneumothorax, dorso-axillary in position. No succussion splash could at any time be obtained. Exploratory puncture gave a seropurulent fluid, which contained pneumococci. There were at no time any signs of tuberculosis. As suffocation was marked, pleurotomy was performed, drainage and gauze being left in the wound. The dyspnea disappeared and she grew gradually better. But the pneumothorax increased. She returned to Italy, after having a simple pneumothorax for 38 days, for no liquid was ever found in the pleura. Galliard explains the condition by supposing a previous pneumonia, which had opened into the pleura. No tubercle bacilli were found in the sputum. The expectoration, which had been purulent and fetid, became clean mucus, without pus having been evacuated from the lung or pleura. Dr. Chaffard related a similar case which, at autopsy, showed an interlobar empyema as the cause. He suggested that this might also have been the case in Dr. Galliard's patient. [M. O.]

Syringomyelia With "Thorax en Bateau" and Tropic Disturbances Resembling Myxedema.—In the *Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, (1901, No. 10), Paul Sainton and Jean Ferrand report the sixth case of "thorax en bateau," in a woman of 56, with syringomyelia, which had begun over 30 years ago. All four extremities are now affected, and there is some scoliosis. There is no pain, and she feels pins, but the thermic sense is abolished. There is some atrophy of the muscles, the upper sternum sinks in, forming the "thorax en bateau," and the skin is thick, almost myxedematous. The deformity of the sternum is due to a tropic bony change, like osteomalacia. The myxedema-like changes are secondary to the long standing syringomyelia. [M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Resignation of Dr. J. Madison Taylor.—Dr. J. Madison Taylor has resigned from the Professorship of Diseases of Children in the Philadelphia Polyclinic, where he has taught post-graduate students for about 15 years.

Dr. J. L. Forwood, Chester, has been re-appointed a member of the State Quarantine Board.

New Site for the Veterinary Department of the University of Pennsylvania.—It is reported that the University of Pennsylvania Veterinary Department will be moved to Thirty-ninth and Woodland avenue, instead of to the Flower Farm, on the West Chester Pike, as formerly intended. The reason assigned for the change in plans is that the department would be too inconvenient for the public on the West Chester Pike, and too far from the University for the students. It is also stated that the work on the new \$60,000 buildings will begin in October.

Resolutions by the Medico-Legal Society of Philadelphia.—The following resolutions were adopted at a recent meeting of this society:

Whereas, the advertising of abortionists and their drugs as well as other disreputable secret medicines has for years been a notorious disgrace to the newspaperdom of this city—an evil seemingly without redress, and

Whereas, The Philadelphia "Times" under its new ownership has declared for a high ethical plane, avoiding all sensationalism while at the same time furnishing "all the news that is fit to print," excluding all medical and other questionable advertisements—so as to make it indeed a newspaper fit for the family circle, therefore be it

Resolved that the Medico-Legal Society of Philadelphia highly approves of the advanced stand taken by "The Times" and urges upon the medical profession generally its active support in aiding to carry out that journal's elevated ideals.

Resolved, further, that the medical periodicals of this city be requested to publish the foregoing in their next issue and that, at the coming meeting of this organization, the Secretary report as to which of these, by printing it, have assisted in furthering so desirable a public movement.

The White Haven Sanitarium for Consumptives has been opened for the reception of patients, of which but 20 can be admitted at present.

Marcus Hook for Carlisle.—The Board of Health of Carlisle has secured the right to use the quarantine buildings at Marcus Hook for small-pox cases.

Vital Statistics of Philadelphia for the week ending July 6th, 1901:

Total mortality	447	Cases.	Deaths.
Inflammation of the appendix 1, bladder 1, brain 13, bronchi 5, heart 5 kidneys 19 larynx 1, liver 1, lungs 16, peritoneum 1, pleura 1, stomach and bowels 45, veins 1 marasmus 36, inanition 21, debility 3.....	170		
Tuberculosis of the lungs	70		
Apoplexy 16, paralysis 3	19		
Heart-disease of 26, fatty degenera- tion of 2	28		
Uremia 18, Bright's disease 6, dia- betes 7	31		
Carcinoma of the bowels 1, breast 1, stomach 7, uterus 2, liver 3....	14		
Convulsions 7, puerperal 1	8		
Diphtheria	36		
Softening of brain	5		
Typhoid fever	117		
Old Age	10		
Scarlet fever	33		
Abortion 1, alcoholism 1, burns and scalds 1, casualties 10, cholera in-			

fantum 27, cholera morbus 1, cir-
rhosis of the liver 3, consumption
of the bowels 1, cyanosis 2, di-
arrhea 1, drowned 8, dysentery
6, epilepsy 1, gangrene 2, hernia 1,
jaundice 2, locomotor ataxia 1,
malarial fever 1, neuralgia of the
heart 1, obstruction of the bowels
2, puerperal fever 1, purpura hem-
orrhagica 1, rheumatism 1, scler-
osis of liver 2, septicaemia 3, sui-
cide 4, sunstroke 2, teething 2,
tetanus 1, ulceration of stomach 1,
whooping cough 14

Cases. Deaths.

NEW JERSEY.

Ex-Governor Newell Dead.—Dr. Wm. A. Newell, ex-Governor of New Jersey and Washington Territory, died on August 8th, aged 84, at his home in Allentown, N. J. Governor Newell, who was a practicing physician, was born in Ohio, and came to New Jersey when quite young. He was a member of Congress from that State from 1847 to 1851 and during that time was instrumental in establishing the life-saving system of the Federal Government. He was elected Governor of New Jersey in 1856 on the Republican ticket and was again a candidate against General McClellan, but was defeated. During the administration of President Hayes, Dr. Newell was appointed Governor of Washington Territory, and from that time until about three years ago made Washington his home.

NEW YORK.

Gastrectomy on a Dog.—At the New York Veterinary Hospital an operation for complete removal of the stomach, for malignant disease, was recently performed on a fox terrier, which was a great pet in the family owning it. The animal is reported to have made an excellent recovery.

University of Buffalo.—The Medical Department of the University of Buffalo has received \$50,000 for the purpose of erecting a laboratory to be devoted entirely to research work. It will be known as the Gratwick Research Laboratory.

Dr. Alvin A. Hubbell, for several years associate editor of the *Buffalo Medical Journal*, has resigned from the editorial staff of that journal.

WESTERN STATES.

Dr. Sanford Riddell, of Chippewa Falls, Wisconsin, one of the oldest physicians in that State, recently died from apoplexy while attending the meeting of the Inter-Counter Medical Society, at Duluth.

Crusade Against Mosquitoes in Chicago.—It is reported that the Castor bean plant which was found by Professor Frederick Starr, of the University of Chicago, to be quite efficacious in driving away mosquitoes, will be employed in Chicago, for banishing the pests from the parks of that city.

The Oklahoma Medical Association.—The Oklahoma Medical Association will convene at Oklahoma City, November 13th, 1901. Dr. R. D. Love, of Perry, Okla., is president; and Dr. E. O. Barker, of Guthrie, is secretary and treasurer.

A Medical Martyr.—T. L. Monson, State Dairy Commissioner of Colorado, professes himself ready and willing to be inoculated with the germs of animal tuberculosis and submit to any test that may be imposed by a committee of surgeons and specialists, provided a suitable provision is made for his family in case the experiment should have a fatal termination. He is an ardent advocate of the theory advanced by Koch regarding the reciprocal communicability of bovine and human tuberculosis.

Rocky Mountain Sanitarium.—An organization has been formed at Denver, of physicians and others with the object of establishing an industrial sanatorium in the Rocky Mountains.

A Kansas Decision.—The Kansas State Board does not regard the Physio-Medical Institute, of Kansas City, as standard, and the attorney general upholds its decision.

The Bacillus Polymorphus.—Dr. C. J. Keenig, formerly

of San Francisco, but now of Paris, is reported to have discovered a new bacillus, which he has named the "Bacillus Polymorphus," occurring in what is claimed to be a new disease of the throat, which has been given the name "Eroso Membranous Angina."

Dr. Charles F. Dutton, who has been Professor of the Theory and Practice of Medicine in the Cleveland College of Physicians and Surgeons for seventeen years, recently resigned.

The American Association of Official Surgeons will hold its next annual meeting in Chicago, September 18th and 19th, 1901.

The Lane Medical Lectures.—We are requested to call attention to the sixth course of the Lane Medical Lectures in Cooper Medical College, inaugurated in 1896, will be given in 1901 by Mr. Malcolm Morris, F. R. C. S., Edinburgh, the subject to be: **The Pathology of the Skin in Relation to Certain Social Problems.** These lectures will be given on the days and hours as follows: September 2, 11 A. M., Introductory; Social Aspects of Skin Diseases; General outline of the subject. September 2, 8 P. M., Inoculable Diseases of the Skin; Animal Parasites; Scabies, pediculosis; Vegetable Parasites; Ringworm; Favus; Recent Researches in Fungi producing them; Need of Special Schools for Ringworm Children; The Hygiene of the Barber's Shop. September 3, 11 A. M., Local Inoculable Diseases; Contagious Impetigo and Syphilis; Boils; Carbuncles; Acne; Actinomycosis; Elephantiasis; their Prevention and Treatment. September 3, 8 P. M., General Inoculable Diseases of the Skin; Tuberculosis; the Part Played by the Skin in its Dissemination; the Crusade for its Extirpation. September 4, 11 A. M., Lupus; the Light Treatment; other Modern Treatments. September 4, 8 P. M., Syphilis; the International League; Leprosy in the Past and in the Present. September 5, 11 A. M., Affections of the Skin dependent on Nerve Disorder; Prurigo and other Itching Affections; Mental effects of Cutaneous Irritability; Skin Diseases in the Insane; Erythema; Lupus Erythematosus; Rosacea; Herpes Zoster; Pemphigus. September 5, 8 P. M., Hysterical Edema; Feigned Eruptions; Stigmata; Bloody Sweat, Dermographism; Diabolic Marks. September 6, 11 A. M., Diseases of Unknown Causation; Eczema; Psoriasis; Pityriasis Rubra. September 6, 8 P. M., Malignant Diseases of the Skin; Epithelioma Cutis; Rodent Ulcer; Röntgen Rays Treatment; Mycosis Fungoides.

SOUTHERN STATES.

The East Tennessee Medical Society will meet in annual session at Newport on Thursday, September 26th, continuing two days. Dr. D. M. Miller, of Indian Springs, is President, and Dr. C. J. Broyles, of Johnson City, Secretary.

Dr. J. H. P. Wise died July 9 at Morgan City, aged 56 years, after twenty years of practice at that place.

Election of Officers at Tri-State Medical Association.—The Tri-State Medical Association, composed of physicians of Western Maryland, West Virginia and Western Pennsylvania, elected the following officers at its recent meeting at Cumberland, Md.: President, Dr. William F. Barclay, Pittsburg; vice-presidents, Dr. Henry W. Hodgson, Cumberland, Dr. Frank L. Baker, Burlington, W. Va., and Dr. Bruce Lichty, Meyersdale, Pa.; recording secretary, Dr. Percival Lantz, Alaska, W. Va.; corresponding secretary, Dr. Frederick W. Fochtman, Cumberland, and treasurer, Dr. E. B. Claybrook, Cumberland.

Mississippi Valley Medical Association.—The next annual meeting of the Mississippi Valley Medical Association, under the Presidency of Dr. A. H. Cordier, of Kansas City, bids fair to eclipse all previous ones in attendance as well as scientific merit, as the following preliminary program will show: Put-in-Bay is an ideal place of meeting, the Hotel Victory a magnificent meeting site. The address in Medicine will be made by Dr. Frank Billings, of Chicago; the address in Surgery by Dr. Reginald Sayre, of New York City. The profession is cordially invited to attend this meeting. No title can be received after August 20th for publication on the final program.

Crusade Against Mosquitoes.—The New Orleans Board of Health has decided to begin a campaign against mosquitoes. Beaumont oil can be obtained at a minimum cost and will be used extensively. The Board will issue circulars to householders asking their coöperation.

The Presbyterian Hospital, Atlanta, has been open since

a month with a beginning capacity of 25 to 30 beds. Its medical staff consists of Dr. Marion McH. Hull, chairman, and Drs. Stephen T. Barnett, Cyrus W. Strickler, James N. Ellis, Edward G. Davis, Miller B. Hutchins, Michael Hoke, John L. McDaniel, James McF. Gaston, Jr., Arthur G. Hobbs, James M. Crawford, and Walter B. Emory.

CANADA.

Meeting of the Ontario Medical Association, held at Toronto, June 19th and 20th. (Conclusion.) Discussion on Gastric Ulcer.—*Surgical Aspect.*—Dr. Henry Howitt, Guelph, conducted this part of the discussion and said, did it never strike you as being peculiar that the best remedies, nitrate of silver and so forth, are germ destroyers? He first took up the procedures for dealing with the ulcer or its results, in which perforation is not a factor. In all the operative procedures it was essential to prevent infection of the wound, the stomach should be thoroughly washed with aseptic water, by means of a siphon tube, immediately before the anesthetic is administered. It is not necessary to make the abdominal incision extensive, the length of the incision would depend upon the amount of contraction and it is sutured in such a manner that when closed the line of union is at right angles to the original incision. This gives excellent results when properly done. Adhesions render this ideal operation impracticable. The first successful operation was performed in Toronto, 1894, by Dr. Atherton. Up to last September in the neighborhood of 300 operations were reported with a mortality of a little over 45 per cent. Dr. Howitt then referred to cases in his own practice. With regard to the treatment, Dr. Howitt said that as soon as we are satisfied that perforation has taken place, referring to acute cases, he believes it is good practice to give morphia hypodermically, and it further lessens the amount of the anesthetic in the opinion of many. Success largely depends on the shortness of time before operation; delay is dangerous. It is Dr. Howitt's practice to eviscerate the bowels; one or more small incisions in the prominent coils soon overcome the distension, and each one is closed before another is made. Attention is now turned to the stomach and the part brought into the wound. The ulcer is incised and the opening closed with two or three layers of sutures. When the trouble is in the posterior wall it may be impossible to excise it, in which case it can be generally inverted and closed by layers of sutures. The abdominal cavity should be thoroughly flushed with a stream of saline solution. When drainage is necessary the tubes or gauze should not be introduced through a large wound. The object should be to have primary union to take place in the incision.

Vaginal Section, Exploratory and Operative.—Dr. T. Shaw Webster read a paper with the above title describing several operations performed in that way, one being for ectopic gestation. He reported good success in them from the vaginal route.

The Roentgen Rays in the Diagnosis of Urinary and Biliary Calculi.—This paper, X-ray photos and specimens of calculi, which proved a very interesting demonstration, was presented by Dr. S. Cummings, of Hamilton.

Preliminary Report on the Relations of Hyperchlorhydria to "Bilious Attacks," Some Forms of Eczema, Gout and Muscular Rheumatism.—Dr. Graham Chambers, Toronto, stated that on several occasions he had examined the gastric contents of patients of apparently normal digestion and found hydrochloric-acid, although in some of them there was a history of "bilious attacks," which were probably attacks of hyperacidity. He considers that the gastric distress, which is present in these cases, is more or less due to the hyperesthesia of the mucous membrane of the stomach, as well as to the excessive acid contents. The commingling of these two neuroses, hyperchlorhydria and hyperesthesia gastrica, makes an investigation into the relations of the former to "bilious attacks," eczema, muscular rheumatism and gout a very definite one, but he cannot but think that a general irritable condition of the gastric nerves must produce some changes in the sympathetic and cerebro-spinal centres, which would no doubt lead, or tend to lead, to diseases in other organs. Dr. Chambers' attention was first called to this subject about two years ago, when he observed that the internal treatment, both dietetic and medicinal, which he was accustomed to give in cases of hyperchlorhydria, was approximately the same as that which he was using in some forms of acute eczema, and in both cases it gave

very satisfactory results. In his experience "bilious attacks" are very frequent in cases of chronic hyperchlorhydria; he has also found that symptoms of indigestion are of frequent occurrence in eczema, and are usually of a character which indicates hyperchlorhydria. He has examined the gastric contents of six cases of eczema, with symptoms of dyspepsia, and in five of these there was an excess of HCl in the gastric contents. He gave notes of cases in illustration of his researches. "Acidity" is a common symptom in gouty subjects, and Dr. Chambers believes that a thorough investigation of the subject would prove that the "acidity" of the gastric contents is not due to organic acid at all, but that hydrochloric acid will be found to play an important part in it. With regard to muscular rheumatism, we know very little about the etiology of it. Clinically, we have found that muscular rheumatism and gout are in some way related; and in regard to relations of hyperchlorhydria and muscular rheumatism, Dr. Chambers has observed that they are frequently associated, but whether the muscular rheumatism is the result of the hyperchlorhydria, he is at the present time unable to say.

Medical Treatment of Surgical Tuberculosis.—Dr. W. B. Thistle, Toronto, said: It is important to remember this fact, that there is no difference in the nature of the disease, whether considered surgically or medically, and especially is this so when we come to consider treatment. We hear on all sides that it is a curable disease, and complete cure often now happily results from medical treatment. Dr. Thistle has observed that tubercular cases requiring surgical treatment in the great majority receive little or no medical treatment. The subject of surgical tuberculosis should have the fullest advantage of sunshine and fresh air as well as those suffering from the disease in its medical aspect.

Treatment of Post-Operative Peritonitis.—By Walter McKeown, Toronto. The paper suggested that this condition should be treated by the use of decinormal salt solution, either subcutaneously or intravenously, and enemata of strong solutions of sulphate of magnesia. The toxins will dialyze; the antitoxins will not. If, then, the toxins can be eliminated with sufficient rapidity, the disease will limit itself as a result of the formation of antitoxin together with the plugging of the peritoneal lymphatics. The blood is diluted by the addition of the salt solution, and this is drawn out into the rectum by means of a higher osmotic pressure carrying the toxins with it. He claims that even with a condition of paralysis of the bowel, toxins will dialyze in this way. He suggests that if a patient were placed in a salt bath, the toxins would probably osmose directly through the skin. That osmosis does not take place from without in through the skin, does not prove that the reverse process will not occur. Osmosis is known to take place much more rapidly in one direction through the shell membrane of the egg than the other.

The Following Officers were Elected: President, Dr. N. A. Powell, Toronto; First Vice-President, R. Ferguson, London; Second Vice, R. W. Garrett, Kingston; Third, L. C. Prevost, Ottawa; Fourth, R. L. Turnbull, Goderich; General Secretary Harold C. Parsons, Toronto; Assistant, George Elliott, Toronto; Treasurer, A. R. Gordon, Toronto.

Resolution on Vaccination.—Resolved, That the Ontario Medical Association desires hereby to re-assert the opinion of the medical profession of this province:

1st. That the principles of Jennerian vaccination against smallpox, which have been now attested by the experience of more than a century, are scientifically correct.

2nd. That in order to carry out the protection through vaccination against smallpox it is necessary that the lymph used in the operation be of normal quality, and that this can be shown only by a proper amount of systemic reaction to the vaccine, as determined by the character of the vesicles, and that the absence of a normal reaction, as shown by the presence of vesicles, is no positive evidence of the immunity of the person either against vaccinia or smallpox.

3rd. That this Association emphasizes the urgent necessity that the scarification of the skin be sufficiently extensive to secure such reaction, and to this end recommend that from three to five insertions each of a quarter of an inch square be made in each vaccination. This was carried.

Women's Medical College of Toronto.—Dr. Graham Chambers has been appointed Professor of Dermatology and Assistant Professor of Clinical Medicine.

Surgeon Major I. Knight Riddall, of Toronto, Canada, has been recommended for the V. D., a new decoration for the officers of the "Colonial Auxiliary Forces" which Her late Majesty the Queen was graciously pleased to institute. The doctor has served in the Canadian Military Forces for over twenty-six years consecutively, receiving during that time the Medal for 1866, and in his younger days served in the "Army Hospital Corps," at the Crimea in 1855 and 1856, receiving the Medal and Clasp for same.

Dr. F. W. Harvey has been appointed surgeon to the Ophthalmological Department of the Royal Victoria Hospital, of Montreal.

MISCELLANY

Medical Schools Ordered in Turkey.—The Sultan of Turkey has ordered the establishment of medical schools at Bagdad, Damascus, and Smyrna.

A Unique Contest.—According to an exchange, it is said that Dr. Tanner, of fasting fame, now sixty-eight years old, has challenged the brewers of Denver to a fasting contest. Six men are to drink beer only, and he is to drink water. The brewers have agreed to the contest.

Thermometers in Guatemala.—The natives of Guatemala who suffer from torpid livers, regard metallic mercury as a specific, and it is reported that some of them will resort to stealing thermometers for the purpose of obtaining the mercury.

Melena Neonatorum.—Holt reports a case of frequent and persistent vomiting of blood in a robust new-born infant, apparently cured by the administration of suprarenal extract in grain doses every hour.

Official List of the Changes of Station and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Hospital Service for the 7 days ended August 8, 1901.

- J. M. GASSAWAY, surgeon, relieved from duty at San Francisco, Cal., and directed to proceed to St. Louis, Mo., and assume command of the service, relieving Passed Assistant Surgeon W. G. Stimpson—August 21, 1901.
- W. P. McINTOSH, surgeon, to proceed to Jasper, Georgia, for special temporary duty—August 8, 1901. Granted leave of absence for 30 days from August 24—August 8, 1901.
- W. G. STIMPSON, passed assistant surgeon, upon being relieved by Surgeon J. M. Gassaway, to proceed to San Francisco, Cal., and assume command of the service—August 2, 1901.
- J. A. NYDEGGER, passed assistant surgeon, granted extension of leave of absence, on account of sickness, for thirty days from August 10—August 7, 1901.
- J. M. HOLT, assistant surgeon, granted leave of absence for one month from August 15—August 2, 1901.
- E. B. HALLETT, acting assistant surgeon, granted leave of absence for 7 days from August 10—August 8, 1901.
- E. B. SCOTT, hospital steward, granted leave of absence for 6 days from August 7—August 2, 1901.
- CHARLES SLOUGH, hospital steward, granted leave of absence for 14 days from August 6—August 7, 1901.
- G. A. McGRIS, hospital steward, relieved from duty at New York, N. Y., and directed to proceed to Havana, Cuba, and report to the Chief Quarantine officer for duty—August 5, 1901.
- W. C. PHILLIPS, hospital steward, relieved from duty at Chicago, Illinois, and directed to proceed to the Mullet Key, Florida, quarantine station, and report to the medical officer in command for duty and assignment to quarters—August 8, 1901.

PROMOTION.

Hospital Steward E. P. Olsen promoted and appointed a clerk of Class 2 in the office of the Surgeon General, U. S. Marine Hospital Service, July 16, 1901.

RESIGNATION.

Acting Assistant Surgeon E. A. Smith resigned to take effect from and after July 31, 1901.

Changes in the Medical Corps of the Navy. For week ending August 10, 1901.

SURGEON F. J. B. CORDEIRO, ordered to the Pensacola Navy Yard—August 7.

P. A. SURGEON D. H. MORGAN, detached from the Navy Yard, Pensacola, Fla., and ordered to the Naval Hospital, Norfolk, Va.—August 7.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended August 10, 1901.

SMALLPOX—United States and Insular.

			Cases	Deaths
ALASKA:	Klukswan	July 26, present.

GREAT BRITAIN.

New Hospital in Scotland.—A new hospital for tuberculous patients is about to be built near Aberdeen, Scotland, with money obtained entirely by voluntary contributions.

Against the Plague.—The London County Council has appropriated a sum equivalent to \$250,000 as a precautionary measure against the plague.

The "Baly Gold Medal."—The "Baly Gold Medal" which is presented every alternate year by the Royal College of Physicians of London for special distinction in the science of physiology, has been this year awarded to Dr. F. W. Pavy, Fr. R. C. P., F. R. S., consulting physician to Guy's Hospital.

Death from Cocaine Poisoning.—According to the *Medical Press and Circular*, an inquest was held last week at Cromer on the body of a young married woman who had succumbed to the effects of cocaine injected in view of a dental extraction. The assistant, an unqualified man, made three injections, equivalent to one grain of the alkaloid, and shortly after the teeth had been extracted convulsions set in, and death supervened within an hour without consciousness having been regained. It is remarkable that death

should have resulted from this comparatively small quantity. According to Dr. Murrell recovery has followed the injection of as much as fourteen grains, though anything over half a grain may give rise to very unpleasant symptoms of cardiac oppression. The most unsatisfactory feature of the case is the administration of the drug by an unqualified assistant, who ran some risk of being committed for manslaughter but the jury tempered justice with mercy by describing it as an accidental occurrence.

CONTINENTAL EUROPE.

Koch's Theory is being Investigated by Germany.—It is reported that Professor Koch's experiments with human and bovine tuberculosis were known for some time by the German government, which had appointed, at his request a commission of experts to examine the results, the commission including Professor Virchow and Pollinger. Warning has been given that the difference between human and bovine tuberculosis has not yet been definitely established, and that precautions for preventing the spread of the disease by butter and milk can not yet be abandoned.

New Medical Journals.—A journal exclusively devoted to military medicine and surgery has begun to be published in Paris under the name of *The Caducée*. A new periodical devoted to biochemistry has been founded in Strassburg by Professor F. Hofmeister. It will be known as the *Beiträge zur Chemischen Physiologie u. Pathologie*.

The University of Zurich has just acquired a new addition to its anatomical building. In this addition is a dissecting room with overhead light to accommodate two hundred students, and on the floor below a microscopical room of the same size. There is also an elegant little demonstration room with overhead light, a laboratory for anthropology, and a laboratory for advanced embryological study, together with a suite of rooms for the director. The old part of the building will be rearranged for a large lecture room, a reading and study room for the students, a museum, and the laboratories for the assistants. The courses given in Zurich in macroscopic and microscopic anatomy are amongst the most thorough in Europe.

Dr. Harper, of Madison, Wis., has been visiting the surgical clinics in London, Paris, Lausanne, Berne, Zurich, Heidelberg, Bonn, and Berlin. He seems to think the German (and Swiss) surgeons superior to the English and French, especially in their asepsis.

Professor Uhthoff, of Breslau, was recently elected Privy Medical Counsellor.

Serotherapy in Malignant Tumors.—G. M. Vlaeff, in a paper read before the Progooff's Russian Surgical Society (*Bohitchnaya Gazeta Bolikina*, Vol. XII, No. 21) claimed to have discovered a serum possessing curative properties in cases of malignant growths. In four cases of the latter affection he isolated from the tumor blastomycetes, in pure culture in two. These were passed successively through birds, and a serum was finally obtained from geese, which was employed for therapeutic purposes. In one case of epithelioma of the lip with secondary involvement of the glands, the serum was injected every fifth day, producing a local as well as general reaction. The former was characterized by a clearing up of the ulcer and a diminution of the infiltration of the lip; the latter by a general improvement of the condition of the patient. As soon as the local conditions improved, the patient was operated on, with favorable results. In the second case the patient suffered from an inoperable carcinoma of the breast. Five injections of the serum improved the patient's condition to such an extent that she was successfully operated on. In a third case of carcinoma of the tongue the ulcer cicatrized completely after two months treatment. In a fourth case of carcinoma of the breast of the size of an orange, 13 injections reduced the growth to one-third, while the infiltrated glands became normal. In summing up the results of his experiments, the author claimed that: (1) in incipient stages a complete cure may be accompanied by the serum; (2) if the disease is advanced but there is as yet no metastasis, the injection of the serum will check the progress of the disease by encapsulating the growth and thus prolong the life of the patient; and (3) if the disease is far advanced and metastatic growths developed in other organs, the serum will diminish the pain, produce sleep and improve the nutrition of the patient. [A. R.]

3.—Williams classifies the climates that are considered beneficial to consumptives as (1) marine climates, (2) dry warm climates, partly inland and partly marine, and (3) mountain climates. The resorts on the south coasts on the British and the Irish channels are suitable for the majority of the cases of chronic pulmonary tuberculosis, particularly for the strumous forms. The warm climates of Madeira, the Canaries and the West Indies have not, in the experience of the author, proved beneficial in consumption. Sea voyages as taken now-a-days are not very beneficial, because the route through the Suez Canal and the Red Sea exposes the patient to extreme and rapid vicissitudes of temperature. The lack of opportunity for exercise and occupation are other detracting features. Sea voyages, under certain conditions, however, taken in sailing vessels, are beneficial (1) in cases of hemorrhagic phthisis, in which large hemorrhage accompanies small areas of tubercularization; (2) in scrofulous or strumous phthisis, in which the lung disease is accompanied by strumous gland or joint affections; (3) in cases of chronic cavity, in which the tuberculous disease is unilateral and quiescent. In order to ensure the success of a sea voyage the patient must be certain of good and abundant food, of proper cabin ventilation, and the cruise should be principally in temperate climates and not in torrid ones. The dry, warm climates include the desert and the borders of the Mediterranean basin. The desert climate is characterized by dryness, warmth, sunshine, great radiation and, consequently, great contrasts between day and night temperatures and also by the purity and asepticity of the atmosphere. It is a climate in which life in a tent is not only possible but also pleasant. The diminution of cough and expectoration is sometimes very marked and as a rule catarrh disappears. The climates of the Mediterranean basin are, as a rule, cooler, more moist and more stimulating than those of the desert, but they are liable to greater changes of weather if not of temperature. A large proportion of the consumptive patients that are sent to these resorts consult the local medical man but once and then go their own very bad way, committing numerous acts of imprudence, and thus lose all the advantages that they expect to obtain. Consequently, the patient often returns home worse than when he left. These stations are likely to prove beneficial to cases of phthisis in which inflammatory processes have played a large part in predisposing to the disease, to cases of strumous phthisis, of laryngeal phthisis, of unilateral tubercularization and to the large class of patients who, either from the extent of the disease, feebleness of circulation or advancing years, are unable to endure the rarefied atmosphere and cold of high altitudes. Mountain or high altitude climates are characterized by diathermancy (Denison), by which the sun's rays are transmitted through the attenuated air, producing a difference between the sun and the shade temperatures of 1°F. for every rise of 235 feet; by their asepticity; and by their physiological effects on the human body, as demonstrated by the tanning of the skin chiefly by the ultra-violet solar rays, the effect on the circulation and the respiration. The author concludes that high altitudes, on account of the respiration of the rarefied atmosphere, produce hypertrophy of the healthy lung and local pulmonary emphysema around the tuberculous lesions, giving rise, in due time, to thoracic enlargement. It is possible that the arrest of tuberculous disease is at least partly due to the

pressure exercised on the tuberculous masses by the increasing bulk of the surrounding lung tissue, which by emptying the bloodvessels promotes caseation of the tubercle. These changes are accompanied by general improvement in digestion and assimilation, the cessation of all symptoms of disease, the return of the natural functions, gain of weight, of color, of nervous and muscular activity and of respiratory and circulatory power. Arrest of disease takes place in 58% of the tubercularization cases and great improvement in 87%. In cases in which there is excavation, arrest occurs in 21% and great improvement in 61%. The high altitude climate is especially beneficial in hemorrhagic phthisis and in phthisis in which the hereditary predisposition is strongly marked. It is well suited to chronic tuberculosis of the lungs in general, provided the extent of lung involved is not too large or the disease accompanied by much fever. The climate is contraindicated in acute phthisis, in catarrhal phthisis, in laryngeal phthisis, in fibroid phthisis, in phthisis accompanied by great nervous irritability, in patients with double cavities and in all patients whose pulmonary surface has been so much reduced that it does not suffice for complete respiratory purposes. The comparison of the results obtained in the various climates show that high altitudes are easily the best to which to send tuberculous patients. Climate is a most potent weapon in the treatment of pulmonary tuberculosis, as shown by results, and also because it gives invaluable assistance to hygiene and medicine. According to Yeo the objects of treatment by climate in cases of pulmonary tuberculosis are: (1) To arrest catarrhal conditions of the air passages, (2) to improve nervous and circulatory tone, (3) to increase the activity of the digestive functions and thus stimulate nutrition by promoting the desire and increasing the power to take exercise, (4) to raise the moral tone by affording a clear, bright and cheerful environment and (5) to diminish by its asepticity bacterial activity. It must be a question for consideration whether the so-called open-air treatment without regard to suitable climatic conditions will do all this. It should be our object, when practicable, to place the consumptive patient under conditions and in circumstances in which, without risk or injury, he may obtain the most complete and perfect aeration of the lungs possible. It is difficult to establish any precise and rigid classification of the cases best suited to particular places, because in many cases, and especially in the very early cases and in quiescent chronic cases with a limited area of local disease the patients will do well and obtain arrest of the disease in a variety of places with somewhat different climatic conditions. In the opinion of the author the value of the ocean voyage has been greatly overestimated and its serious drawbacks insufficiently realized. Patients seen at the very commencement of the disease and who are otherwise in good health may be permitted a certain amount of choice in the selection of a climate, provided it allows of many hours spent daily in the open air and that they are placed under proper hygienic conditions. Patients who are suffering from a progressive febrile form of tuberculosis should repose in bed or on a couch at home in the best condition possible for the free access of air and sunshine to their apartments. Patients in the advanced stages of the disease are best off at home, if the conditions of home life are favorable, or in warm marine climates with cheerful surroundings if change is advisable. For the catarrhal forms warm, soothing climates, such as Madeira or Teneriffe, are the best. For rheumatic or gouty patients of the fibroid or pleurogenic type, dry, marine climates or the desert climate are most suitable. Scrofulous patients do well in fairly bracing marine climates, if they are free from catarrh; if catarrh is present, mild marine climates should be prescribed. For the majority of the other patients with moderately advanced cases, with the limitations already mentioned, the climate of the high mountains above the cloud belt is the most curative. The author does not believe that hemorrhagic cases should be placed in a group by themselves, because every case complicated by hemorrhage must be considered separately. [J. M. S.]

 9. Tuberculin as a Diagnostic Agent. HAROLD SESSIONS.
- 1.—See abstract in *Philadelphia Medical Journal*, August 3, 1901.
 - 2.—Brouardel in an address delivered at the 3d general meeting of the British Congress on Tuberculosis, on July 21, directs our attention to the **prevention of tuberculosis in the different civilized countries**. The mortality from this disease varies in them, and it has been variously estimated as being one-sixth, one-fifth, and sometimes one-fourth of the total mortality. He points out that for many centuries the general opinion has been that the disease was incurable and therefore the struggle against its spread was considered useless. Villemin is to some extent responsible for the changed view in regard to the hopelessness of the prognosis, for this author, in 1865, demonstrated the contagious nature of the disease, but it remained for Koch to discover the exciting agent of this contagion—a factor which has entirely changed. The author reviews the various steps that have been taken to cure, prevent, and exterminate tuberculosis in different civilized countries. The facts which he has mentioned and the conclusions which he has drawn may be summarized in the single statement that tuberculosis should be universally known as a disease which is avoidable and one which can be cured. When these two points become known, anti-tuberculous efforts will multiply so rapidly and become so efficient that it may be reasonable to prophesy that with this united effort the civilized world will finally succeed in exterminating this scourge. [F. J. K.]
 - 3.—Niven delivered an address before the Tuberculosis Congress on the **Administration of the Manchester Milk Clauses**. The almost complete absence of tuberculous lesions in new-born infants compared with children suffering from abdominal and other tuberculous lesions, leads to the probable conclusion that the food of young children is more liable to produce tuberculosis than the food of adults. This conclusion is greatly strengthened by the experimental evidence presented by Cheveau, Joehne, Woodhead and Mertin. This facts lead the Royal Commission to establish laws excluding the sale of milk from cows affected with tuberculosis of the udder, or those exhibiting clinical symptoms of the disease. The authorities were given power to slaughter the diseased animals, subject to compensation under certain named conditions. The Sanitary Committee of Manchester, in September, 1898, adopted milk clauses which gave the authorities unlimited power to inspect cows on all farms supplying the city with milk, and further provided for the exclusion of milk from animals affected with diseased udders of any kind. Other communities soon followed the example set by Manchester. It was clearly recognized by this time that a clause should be inserted which should provide for the slaughter of cows affected with tuberculous udders. The remainder of the article deals chiefly with the laws and the attempts at establishing laws in order to exterminate tuberculosis from dairy cattle. The author suggests the following: (1) That it should be required by law that cows suffering from tuberculous udders should be slaughtered in the presence of a veterinary surgeon; (2) there should be no restrictions upon the inspection of herds supplying a district with milk; and (3) for the failure to notify the authorities of suspicious conditions of the udder, there should be imposed a penalty. [F. J. K.]
 - 4.—Hope discusses sterilization and pasteurization vs. tubercle free herds. He contends that raw milk is more susceptible to contamination and more exposed to contamination than any other food. Milk from a healthy animal, passing directly at the time of its secretion into the glands into the stomach of a young animal, is bacteriolo-

gically clean and pure. Sterilization, a valuable safeguard against tuberculosis, is of far less advantage in preventing contagion than the procuring of milk from herds free from tuberculosis. It should be our aim to see that the source of our milk is pure, free from tuberculosis. He has no hesitancy in declaring that it is possible, through the enactment of laws, to insure a milk supply from cows free from tuberculosis. The remainder of the article is largely devoted to the consideration of the predisposing causes of tuberculosis in cows. [F. J. K.]

5.—Allen delivered a lengthy address before the Tuberculosis Congress on the **natural immunity from tuberculosis in Natal, South Africa**. This author believes that the situation, topography, and climate of Natal are responsible for this natural immunity, which exists not only in the human race of that country but also in the animals. [F. J. K.]

6.—R. de Josselin de Jong communicated an article to the Tuberculosis Congress on the **treatment of phthisis as a prevalent disease in Holland**. During the last few years sanatoria have been established in the Netherlands, and the results of this plan of treatment may, in general terms, be said to compare with those gained at foreign sanatoria. The beneficial effects which consumptives gain by treatment in a sanatorium are: (1) The improvement in the health of the patient; (2) the subject of hygiene is taught at such an institution, and these teachings are spread amongst the poor and less intellectual classes by these patients. This author makes an earnest plea for the maintenance of the remainder of a family, when the patient admitted is the person upon whom the support of his family depends. The influence brought about by such a plan will relieve and cheer the mind of the patient and greatly influence the prognosis. After the patient has received beneficial effects from the sanatoria he should not return to unhealthy surroundings. With the establishment of sanatoria it should be our duty to improve the houses of the working classes, so that when a patient is entirely or partially cured, he will be able to continue with the hygienic rules of life learned at the institution. [F. J. K.]

7.—Moeller discusses the **relations of tubercle bacilli to other bacteria resistant to acids**, before the Tuberculosis Congress. This author calls our attention to the fact that quite recently micro-organisms have been discovered, which, like the tubercle bacillus, are resistant to acids. Koch contends that while the peculiar reaction of the tubercle bacilli is of value the etiological significance of this micro-organism by no means can be determined by its specific color reaction. Klein and Marmorek have demonstrated that young tubercle bacilli do not resist acids and alcohol, a fact which the latter attributes to the tubercle bacilli not yet being covered with a fatty or waxy envelop, while the former believes the resistance of the micro-organism to acids depends upon the formation of chemical substances by the bacilli, which are wanting in the young organisms. Burrel succeeded in removing the power of resisting acids and alcohol by treating the tubercle bacilli with warm xylol. By this method he modified the tinctorial reaction but did not influence the pathogenic properties. The lepra bacillus, smegma bacillus, and the organism of the avian tuberculosis resemble the tubercle bacillus. The lepra bacillus is shorter than the tubercle bacillus but of more uniform length and stains more readily than the latter organism. The smegma bacillus was discovered by Tabel and Alberez in 1885, in normal preputial smegma. The author mentions that the organism of avian tuberculosis differs from the organism of tuberculosis in mammals in the appearance of the cultures and the temperature conditions. Petri and Rabinowitsch succeeded in finding a bacillus (not the tubercle bacillus) in butter which was resistant to acids and alcohol. Moeller succeeded in cultivating a micro-organism similar to the tubercle bacillus and the grass bacillus II. from milk, and as the grass bacillus is so constantly found in cattle-fodder, he believes we are justified in arriving at the conclusion that the milk and butter bacilli are varieties of the grass bacillus. Morphologically and tinctorially the grass bacillus is identical with the tubercle bacillus. Moeller has given the name "timothy bacillus" to that micro-organism which was first found in timothy grass. The cultural characteristics of the timothy bacillus differ from those of the tubercle bacillus. It may be cultivated upon nutritive media at room temperature—colonies appear after 36 hours. The pathological changes produced in guinea pigs by the timothy bacillus are almost identical with those induced by the Petri-Rabinowitsch butter bacillus. By the injections of

cultures of this micro-organism into the veins and arteries of an animal the pathological lesions which develop are difficult to distinguish from true tuberculosis. Reference is also made to the manure bacillus, a variety of grass bacillus, found in the excrementitious matter of cows and other herbivora. Morphologically and tinctorially the grass bacillus and its varieties, milk and butter bacilli, and the manure bacillus are practically identical with tubercle bacilli. The behavior to temperature and the cultural characteristics of the grass bacillus differ from those of the tubercle bacillus. The very slow growth of the tubercle bacillus and the fact that incubation temperature is most favorable for its growth, places it in a unique position when compared with other acid resisting bacteria. Moeller, Frankel Pappenheim, and Rabinowitch have found bacilli in the sputum of individuals which resembled genuine tubercle bacilli in point of morphology and color reaction. The diagnosis of tuberculosis in the absence of physical signs, and in the presence of finding bacilli resistant to acids in the secretions of the respiratory organs, must be confirmed by cultural characteristics, the tubercle bacillus growing slowly and at its peculiar temperature requirements. The author suggests the following simple method. A small amount of the secretion containing the acid resisting bacilli is mixed with nutritive bouillon and incubated at 30 C. If, at the end of 24 hours, there is an increase in the bacilli resistant to acids it may be inferred that these are not tubercle bacilli. The pseudotubercle bacilli, when inoculated into animals, produce a tuberculous-like disease in a limited number of cases under certain conditions. The tubercle bacillus always produces tuberculosis. Macroscopically pseudotuberculosis of animals bears a resemblance to genuine tuberculosis, differing however, in the fact that pseudo-tubercles are of an inflammatory character and show a tendency to the development of abscesses. In the tubercles are seen the caseous substance, giant cells, and epithelioid cells; these are very rarely found in the pseudo-tuberculosis. If tubercle bacilli and butter are injected into the peritoneal cavity of an animal, a peritonitis is induced which is identical with the inflammation, produced by the injection of the pseudo-tubercle bacilli, and differs entirely from typical tuberculosis. The author concludes the article by stating that the etiological significance of the tubercle bacillus is quite distinctive, and that this organism occupies a unique position among bacteria resistant to acids. [F. J. K.]

8.—Brown gives an account of the post-mortem appearances of bovine tuberculosis, in a paper communicated to the British Congress on Tuberculosis. This lecture was illustrated by 106 lantern slides. He gives a detailed account of the tuberculous lesions of the brain, the eye, the pharyngeal glands, the tonsils, the cervical glands, the heart, the larynx, the lungs, the liver, the spleen, the uterus, the bladder, the udder, and of the bones. This author sets forth a view that the tubercle follicle is composed of leukocytes or phagocytes and that these cells resist the invasion of the tubercle bacilli. In bovine tuberculosis the giant cell is present as a constant and conspicuous feature in the early stages of the morbid processes. This author does not agree with those who hold that the giant cell is an enlarged fixed connective tissue cell, but he believes with Metchnikoff, that this cell is formed of numerous leukocytes. The central portion of the giant cell he states is composed of the debris of dead leukocytes which were engaged in the conflict with the tubercle bacilli, and he regards the zone of leukocytes which are found beyond the giant cell area as having a protective function, and the outermost zone of the tubercles as being composed of leukocytes which are engaged in constructing a fibrous wall to prevent a further advance of the enemy. [F. J. K.]

9.—Sessions writes on the value of tuberculin as a diagnostic agent. He discusses the value of this agent from a practical and commercial point of view, rather than from a laboratory standpoint. He is an ardent advocate of its employment and holds that the incorrect and often contradictory results obtained from its use are due to the following conditions: (1) From the use of old and inefficacious tuberculin; (2) harshly and improperly performed tests; (3) from errors made at the postmortem examination; and (4) from the failure of the operator to understand what he sees. The results of this test as it was employed were excellent. Sessions carefully studied the technique and the results in a large number of cases in the Argentine. He urged the Congress in order to prevent misuse of this valuable diagnostic agent to adopt a plan whereby tuberculin could be supplied from a single central authority, and

further, that a statement of the results should be secured from those who use it. The advantages to be gained from such a method are patent. A properly prepared standard tuberculin could be supplied and much needed statistics could soon be compiled. [F. J. K.]

MEDICAL RECORD.

August 10, 1901.

1. The Propagation of Yellow Fever; Observations Based on Recent Researches. WALTER REED.
2. Empyema of the Antrum of Highmore in Young Infants. EMIL MAYER.
3. The Selection and Sterilization of Muriate of Cocaine for Spinal Anesthesia. WM. C. RILEY.
1. A Case of Primary Epithelioma of the Uvula. SEYMOUR OPPENHEIMER.
5. Multilocular Cyst of the Inferior Maxilla; Operation; Recovery. J. A. OTTE.

1.—Walter Reed contributes a paper on the propagation of yellow fever, including observations based on recent researches. He reviews the question of the mosquito theory of yellow fever, giving full credit to Carlos J. Finlay for the discovery. A series of 16 cases are reported, in which the effort was made to establish the disease experimentally. Of these 16 cases, 12 submitted to the bite of the infected mosquito, and of these, 11 developed the disease. In two the results were negative, and in four cases injected with infected blood, three were positive and one negative. Reed studies the results obtained by Carter at Orwood and Taylor, Miss., in 1898, on the interval between the infecting and secondary cases of yellow fever. 93.7 per cent. of Carter's cases correspond with the mosquito interval; that is, the secondary cases occur at just the interval—thirteen to twenty-three days—when we would expect them to develop, provided the mosquito was concerned in the propagation of the disease. In only one of the sixteen first secondary cases was the interval as short as eleven days and fifteen hours. If the commencement of the attack in this case had been recorded correctly it would indicate that the number of days which we have given as about twelve, would have to be shortened somewhat, probably to ten days. Reed adds that of two of the nurses who remained continuously in attendance upon a case of yellow fever at Quemados, Cuba, one contracted the disease on the fourteenth day after the commencement of the primary case. He concludes by stating that he does not believe we can longer ascribe with confidence any part of the spread of yellow fever, nor can the disease properly be classed as a filth disease. [T. L. C.]

2.—Emil Mayer reports a case of empyema of the antrum of Highmore in a young infant. He states that there are but few reported cases of this affection in the literature, and he gives a résumé of these cases. [T. L. C.]

3.—William C. Riley presents a paper on the selection and sterilization of cocaine for spinal anesthesia. Following his method of dry sterilization, a careful selection is made of muriate of cocaine which is broken in a mortar into moderately fine fragments and heated in a dry sterilizer to 110° C. for about 20 minutes and then blotted in a clean, dry bottle with a tightly fitting rubber stopper. This insures a dry salt to begin with, which is quite essential for the after process. Small graduated vials or tubes, carefully cleansed, dried and flamed, are selected, and when cool such an amount of the cocaine is weighed off into each as will make, when the vials are filled to this mark with sterilized water, a two per cent. solution. The mouth of the tube is then closely stoppered with a plug of freshly dry-sterilized absorbent cotton (150° to 160° C. for one hour). It is then placed in a dry sterilizer and the temperature gradually raised from 145° to 150° C., and maintained at that temperature for from ten to sixty minutes. Ten minutes is usually sufficient time to fulfill all requirements, but there might be a possibility of contamination with certain spores which would require a longer period. After cooling, the vials may be taken out and stoppered with sterilized rubber stoppers, or well-fitting corks which have been plunged in a wax resin mixture heated to 170° C., or the end of the tube may be drawn out and sealed. This method, according to the author, gives perfect sterility and absolute efficiency, and presents the further advantage that the product being dry lasts an indefinite time, and that it is a definite quantity.

[T. L. C.]

4. Seymour Oppenheimer reports a case of **primary epithelioma of the uvula** occurring in a man 81 years of age. On account of the age of the patient the glandular involvement which existed and the general impairment of health, operative interference was not considered advisable. [T. L. C.]

5. J. A. Otto reports a case of **multilocular cyst of the inferior maxilla** occurring in a well-nourished lad of 16. After removal of the tumor it was seen through near the symphysis. In the section fifteen large and small bony cysts were seen, the largest the size of a dove's egg. These did not communicate with each other; besides this, on cutting through the bony portions numerous other cysts were found. These cysts contained a glary brownish fluid. In some cases the walls were smooth, and in other cases lined with interlacing trabecula. The patient recovered. [T. L. C.]

MEDICAL NEWS.

August 10, 1901. (Vol. LXXIX, No. 6).

1. The Condition of the Kidneys with Reference to the Employment of Diuretics. ARTHUR R. ELLIOTT.
2. The Therapeutics of Subacute and Chronic Heart Diseases. THOMAS E. SATTERTHWAIT.
3. Gouty Affections of the Kidneys. RICHARD K. MACALESTER.
4. Uremia and Its Differential Diagnosis. S. D. HOPKINS.
5. The Cardio-Vascular Changes of Renal Disease. J. N. HALL.
6. Renal Functions and Life Insurance. CLINTON G. HICKEY.

1.—A. R. Elliott concludes the following: (1) Except in the case of the irritant epithelial diuretics (turpentine, cantharides, etc.) the entire class of diuretics may be said to exert their effect upon the urine by acting directly through the circulation; (2) owing to the necessity for sparing the kidneys all irritation, drugs given for diuretic purposes should act indirectly rather than directly, consequently the secretory diuretics are contraindicated in irritative and inflammatory renal conditions; (3) In functional urinary disorders diuretics are mainly useful to overcome concentration and hyperacidity of the urine. To accomplish this, simple diluents and salines are best adapted; (4) In acute nephritis saline diuretics are permissible throughout the entire course of the disease and exert a beneficial influence by increasing elimination and clearing the tubes of inflammatory debris. Subcutaneous saline infusion constitutes our most powerful eliminant in desperate cases; (5) In chronic nephritis the cardio-vascular diuretics are most useful, owing to the fact that oliguria and dropsy are usually the result of circulatory failure. The dropsy under such circumstances, being of cardiac origin, may be benefited by cardio-vascular stimulants provided the kidneys are not too badly damaged; (6) Dropsy of purely renal origin is not amenable to favorable influence by diuretics; (7) Although the morbid process in the kidneys may furnish us with our primary inspiration to diuretic medication, it is the condition of the heart and circulatory apparatus in most cases that determines the choice of an agent. [T. M. T.]

3.—R. K. Macalester gives the following pathology of the so-called gouty kidney: It is identical in appearance with the small, red, granular kidney of other origin. It is much contracted with a shriveled granular surface, and the capsules thickened and adherent. The decrease of size is chiefly at expense of the cortical portion. Microscopically, there are present the signs of destruction of the renal parenchyma with connective tissue formation, degeneration of the epithelium of the uriniferous tubules and the glomeruli, and endarteritis obliterans of the larger arteries. Deposits of uric acid and urates, appearing as white streaks in the direction of the tubes in the pyramidal portion and the little white points in the cortical, were attributed to the gouty origin of the trouble, but since these same concretions have been demonstrated in the kidneys of very young children, and in other conditions they cannot be considered pathognomic. Besides the small, contracted kidney, large, and mixed granular forms have also occasionally been met with, and described as dependent on gout. [T. M. T.]

4.—S. D. Hopkins mentions a form of uremia in which the symptoms are very slight, "latent uremia," and due to

complete obstructive suppression of urine. The symptoms are little headache, nausea, pupils contracted, tongue dry, temperature subnormal, weakness and drowsiness and toward the end slight twitching of the muscles. The most trustworthy signs are the contracted pupils, subnormal temperature and no loss of consciousness. [T. M. T.]

6.—C. G. Hickey, in his article on Renal Functions and Life Insurance, has ascertained that about one-sixth of the applications for life insurance are refused, all causes being taken into consideration, and that at least one-fourth of these rejections are based upon the presence of albumin in the urine, although not all of these are suffering from irreparable damage of the kidneys. The question of albuminuria still continues, as it has been, a moot one. The number and variety of the pathological relations under which albumin may appear in the urine compel us to regard it as dependent not only upon inflammation, grave congestions and other coarse organic changes, but upon slight variations in the mechanical conditions of the circulation in the kidney. Excluding accidental admixtures of blood or pus from the bladder or urethra, albuminuria is met with in not only acute and chronic Bright's disease, but in diseases of the heart, lungs, and liver, in peritonitis, pregnancy, abdominal tumors, in most febrile and inflammatory diseases. In many cases of poisoning, cancer, tubercle, and syphilis; in lardaceous disease, in anemia, debility, dyspepsia, scurvy, after paroxysmal hemoglobinuria, in gout, in delirium tremens, in various diseases of the brain and spinal cord, in epilepsy, in certain skin diseases, as well as in apparently healthy persons after bathing, exercise, etc. [T. M. T.]

THE NEW YORK MEDICAL JOURNAL.

August 10, 1901. (Vol. LXXIV, No. 6).

1. Cleft Palate and Its Association with Hare Lip. JOHN H. BRANTH.
2. Acute Lobar Pneumonia: A Pathological and Clinical Study of 120 Consecutive Cases Subjected to Post-mortem Examination. JOHN LINDSAY STEVEN.
3. Suggestions for a Study of Fats in Their Relation to Physiological Chemistry, Therapeutics and Toxicology. JOHN REID.
4. The Home Treatment of Tuberculosis. IRWIN H. HANCE.
5. A New Method of Testing for Lactic Acid. MARK I. KNAPP.

1.—J. H. Branth, in his article on **cleft palate and its association with Hare-Lip**, gives the following varieties of the deformity: (1) The median (intermaxillary). This is so rarely met with that its occurrence has been denied; it comes from failure of the endognathion. Most frequently it involves only the lip, more rarely there is entire absence of the intermaxillary bone and a complete cleft of the palate, hard and soft. This would be a condition of *central cleft*; (2) Ordinary hare-lip (intermaxillary), either unilateral or bilateral, is the usual form. Here there has been a failure of union between the central and outer portion of the upper lip; (3) Facial cleft (intermaxillary). The cleft arises from the upper lip, skirts around the ala of the nose, and reaches to the inner canthus of the eye: It usually involves only the soft parts and not the bone; (4) Buccal cleft (maxillomandibular), or macrostomia. In this deformity there has been a failure of union of the portion of the cheek developed from the maxillary process with that from the mandibular arch (an opening just anterior to the ear); (5) Mandibular cleft, or median fissure of the lower lip, is explained by the failure of the mandibular arch of either side to unite. It is very rare; (6) Cleft palate. The uvula, alone may be involved, or the cleft palate may extend partly or fully through the hard palate. Normally, union takes place from before backward so that incomplete cleft always involves the posterior portion of the palate. Now, when the cleft is complete (often called Wolf's jaw -- *Wolfsraehen*), or, rather, when there is no union of the parts forming the roof and interior wall of the mouth, and the upper lip is also divided, there is a double hare-lip, the intermaxilla being attached to the vomer and carrying the central portion of the lip. Or there may be a single hare-lip, usually on the left side, and then the intermaxillary bone is attached to the right side of the hard palate, projecting more or less in front. Here the vomer is

usually attached to the right side of the hard palate, though it may hang entirely free, and may even extend to the back of the pharynx, dividing that cavity into two.

[T. M. T.]

2. J. L. Steven divides pneumonia into two classifications primary and secondary. By primary pneumonia he means that variety of that disease which begins acutely in the midst of ordinary health and runs the characteristic clinical course. Secondary pneumonia includes those cases in which the pulmonary lesion may be looked upon as the direct result, either of some old standing primary lesion elsewhere, or of septic absorption or insufflation. Macroscopically and microscopically the structural change may be the same in both. He does not believe that it is possible, at present, by the ordinary bacteriological methods to differentiate the two forms. The conditions of the other organs in this disease are the same as are met with in specific fevers. We find cloudy swelling of the liver, kidneys and spleen; especially do we find enlargement of the spleen. The author believes that acute lobar pneumonia is a general disease, and not a local one. His statistics show that 21 died on or before the sixth day; 48 from the seventh to the eleventh day, and that the crisis of the disease occurred on the seventh or eighth day.

[T. M. T.]

3. J. Reid states in his article that iodide of potassium has been used as an eliminator of poisons, and cod-liver oil has been used merely to add fat to an exhausted system. It may well be asked whether the oil is only a fattener, or whether it also serves to eliminate poisonous principles. The use of fat as a vehicle, as a menstruum, in the economy has been neglected, and its elective affinity has been either unknown or ignored. These two functions appear to the author to be highly important to the economy, and to open up a subject well deserving careful study. The use of oleaginous matters in some cases might replace that of iodide of potassium. To sum up: (1) In urinary analysis—oleic acid is useful and speedy in dissolving various principles; (2) in analyzing organs—they may be partly analyzed by acidulating and extracting with supernatant oleic acid, or the fat should be skimmed off and treated with benzene, so as to make complete analysis; (3) fat may be used to eliminate poisons from the body; (4) the elective affinity of drugs may be partly due to their fat affinity; (5) the whole subject of fat in its relation to the economy is worthy of careful study. [T. M. T.]

4.—In the Home Treatment of Tuberculosis, I. H. Hance gives three fundamental needs of patients suffering from the above disease: (1) **Fresh air**; (2) **Good food**; (3) **rest**. Fresh air is required every day and night, the more the better. In winter the room should face south and west, in summer east and south. A fireplace and windows at both sides are advisable. For patients who are bed-ridden, a house with a southern exposure in winter with a piazza where large quantities of sunshine can be obtained and the greatest protection from the prevailing winds. For summer, tent life, night and day, is the ideal one. It is the physician's business to regulate the temperature of the sleeping room, how windows and blinds should be arranged at night, and how long patient should be out of doors, gradually keeping him out longer and longer until he is out the whole day, rain or shine. As to food, if the stomach is delicate, prescribe absolute rest, concentrated liquid food every two hours until 8 P. M., and once during the night, with one evacuation of the bowels daily. Over-feeding is the principle to act upon in all cases, whether feverish or not, whether incipient or advanced, and this is to be kept up until the patient is up to or above his usual weight. It is advised to give three good meals a day with something easily digested between meals and at bedtime. Rest should be absolute in all febrile cases and in all cases at the commencement of treatment for a period of from one to four weeks. Exercise should be controlled in regard to temperature, heart's action, chills, slight suspicions of blood in sputum, loss of or stationary weight and a state of distinct over-fatigue. The author does not think that enough attention is given to the action of the skin. Clothing and bathing are two of the most important aids in producing this action. [T. M. T.]

5.—M. I. Knapp gives a new method of **Testing for Lactic Acid**. For the test a very weak solution of ferric chloride and ether is needed. The strength of the iron solution is 1 to 2,000 freshly prepared. The test is performed as fol-

lows. One cubic centimeter of the filtered gastric juice is put into a cylindrical separatory funnel and to it is added either up to five centimeters. The gastric juice with the ether is then well shaken, by which procedure the gastric juice, if present, is extracted by the ether. This is allowed to remain quiet for a little while to permit of the separation of the two liquids. About two centimeters of the iron solution are put in a test tube of about half an inch in diameter, the iron solution appearing then practically colorless. The test tube is now held inclined and the ether extract is allowed slowly to run from the separatory funnel on the wall of the test tube, which is now turned to a vertical position. At the line of contact of the two liquids appears the canary-yellow ring, which is in very marked contrast with both the subnatant and supernatant fluids. If this canary-yellow ring is not so well distinguished immediately, then the test tube may be looked at again after a few minutes. To see this yellow ring better a white paper is held behind the test tube, our back being turned toward the source of light. [T. M. T.]

JOHN HOMANS.

4. The General Character of the Problems of Public Health Bacteriology. HILBERT W. HILL.

5. Intracranial Pressure After Head Injuries.

WALTER H. CANNON.

2.—There are two instruments that have been devised for the clinical measuring of the blood pressure. The Gartner instrument is by far the simpler, but the Mosso apparatus, if properly used, is more sensitive and exact. Howell and Brush believe that it is desirable, when possible, that the results of one method should be checked by those of the other. Neither instrument can be used successfully for comparative results without careful attention to details.

[J. M. S.]

3.—After a study of the relation of bodily mutilations to longevity, Homans concludes that, as a class, persons who have suffered amputations or other mutilations are not so likely to be long lived as those who are healthy and have not been mutilated. By careful selection, however, many of the mutilated persons might be picked out who would be good subjects for life insurance. [J. M. S.]

4.—Applied bacteriology finds expression at the present time in 4 more or less distinct fields: (1) Industrial bacteriology is concerned particularly with the action of bacteria as they affect certain industries of economic importance. (2) Pathological bacteriology is occupied chiefly with the relations of certain bacteria to the animal body. (3) Water and sewage bacteriology. (4) Board of Health bacteriology. One problem constantly pressing on all health board laboratories is that of sending out early and accurate reports. The promptness of the reports depends largely upon executive arrangements, but their accuracy depends upon complete knowledge and perfect methods. Unfortunately, our knowledge is incomplete and our methods imperfect. We are, therefore, constrained to acquire more information and to improve methods. In diphtheria diagnosis, for example, certain forms of bacilli are found which, while morphologically perfectly familiar, must still be considered as belonging to those forms the true relation of which to the diphtheria bacillus has not yet been determined. It may, at first glance, seem strange that a problem as simple as this one apparently is should be so difficult of solution. But in bacteriology the factors are not yet fully established, and, furthermore, the methods are still imperfect. Therefore it is necessary to impress upon the practitioner that working errors exist and to point out to him the nature of these working sources of fallacy so that he may allow for them and more intelligently interpret the reports that he may receive from the bacteriologist. [J. M. S.]

5. Cannon believes that the problem of the secondary

increase of intracranial pressure after head injuries is essentially the determination of the behavior of brain tissue deprived of its normal nutrition. It has been proved that lack of oxygen causes protoplasm to absorb water. The initial changes in the injured brain are hemorrhage and contusion with thrombi and extravasations. The result of these changes is an impaired blood supply to the injured region and a consequent lack of oxygen. The lack of oxygen causes an increased osmotic pressure within the tissues and a consequent taking up of water from the surrounding plasma. The swelling and edema of the brain after head injuries is not, therefore, due to passive transudation, but is the result of an active process in the tissues themselves, a force many times greater than blood pressure, and amply sufficient to produce all the pressure symptoms and to account for all the signs of intracranial tension which clinical cases of cerebral trauma often manifest. [J. M. S.]

8. Scientific Research; the Indispensable Basis of all Medical and Material Progress. GEORGE BAGOT FERGUSON.

1.—See abstract of *Jour. of Amer. Med. Assoc.*, in *Philadelphia Medical Journal*, August 3, 1901.

2.—A. Stewart Lobingier thinks that when a physician or surgeon speaks of having his patients recover without operation from appendicitis he should bear in mind the sequels of such treatment. These sequels are also apt to follow delayed operations. The formation of pus in large quantities is not necessary to septic metastasis. If the infecting bacteria are active, foci of infection may be set up at distant points within 24 or 48 hours. Intestinal obstruction is the frequent result of waiting for an abscess to be "walled off." The author quotes extensively from literature and refers to several of his own cases to show the bad results of delayed operations. [J. H. G.]

3.—T. A. McGraw reports two cases of vicious circle after gastroenterostomy. This complication occurred in these two cases although they were operated upon after the same manner as many others, where no such complication arose. In the first case the condition was discovered postmortem. In the second case it was diagnosed and operated upon. At the time of the second operation it was found that the afferent portion of the ileum which had been placed upon the left side of the body was now on the right side, in fact, the loop which had been made at the time of the operation was reversed. In order to accomplish this change the stomach had been partly twisted on its axis. The efferent limb of the ileum was found contracted and empty, while the afferent portion and duodenum were enormously distended. The afferent and efferent limbs of the jejunum were anastomosed by means of a Murphy button. The patient made a satisfactory recovery. (To be continued). [J. H. G.]

4.—A. W. Morton, in speaking of the subarachnoid injection of cocain for the purpose of producing analgesia says that in this method "we have a safe and reliable analgesia * * * for the performance of any surgical operation on any portion of the body, regardless of age, sex, or disease, and one which has no contra-indications." The author has followed this method 314 times. In only one instance has he seen alarming symptoms from its use. The ages of the patients varied from 8 to 86 years, and

many of them suffered from well advanced organic disease. The author has been unable to discover any remote complications from the use of the drug in this way. A number of the operations reported by the author were done on parts above the diaphragm. [J. H. G.]

1.—Will be abstracted when concluded.

2.—Thomas B. Fletcher reports two cases of fusel oil poisoning with special reference to the copper reducing substances eliminated in the urine. His conclusions are drawn from the study of these two cases in addition to the study of the effects of the administration of fusel oil to dogs. He states that fusel oil when administered to animals, causes the elimination in the urine of combined glycuronic acid which reduces alkaline, copper and bismuth solutions and acts as a levorotation to polarized rays. When taken by men it acts as a profound intoxicant, causing unconsciousness of several hours' duration. In one of the cases it was followed by symptoms of hemiplegia. In certain cases it has been found to be a profound blood destroyer and causes methemoglobinuria. In both cases reported it caused transitory nephritis. Glycosuria was also produced in both cases, lasting two or three days. In addition to these facts, it was found that the evidence was fairly conclusive that glycuronic acid was present in addition to glucose. [T. L. C.]

3.—Julius Friedenwald discusses dilation of the stomach. He reports a number of cases from the literature together with two cases of acute dilation which were under his own care. As to the etiology of the condition, he believes that acute dilation may take its origin in a certain class of cases from some error in diet, or sudden overloading of the stomach; in another class of cases from a sudden paralysis of the muscles of the stomach, due to a poisoning of the nerve centers. There are certain symptoms characteristic of this trouble. These are the sudden and rapid distention of the stomach, the pain in the absence of peristaltic movements, the absence of vomiting and diarrhea, followed by intense and constant vomiting of very large quantities of greenish fluid and marked by exhaustion of the patient. The author points out the possibility of the occurrence of acute dilation in all cases of acute dyspepsia, indicating the necessity of emptying the stomach quickly. [T. L. C.]

4.—Continued from August 3, 1901). After discussing these two cases McGraw concludes his article with the following:

First.—The "vicious circle" may occur whenever the duodenum becomes permanently distended, even though the efferent limb of the jejunum offers an open passage to the ingesta. In all operations of this kind, therefore, an enteroenterostomy should be added to the gastroenterostomy in order that the duodenum may discharge its contents into the efferent portion of the jejunum.

Second.—It may also occur from obstruction due to spurs, twists, bends or other entanglements of the intestines. As such accidents may arise from a too short afferent limb of the jejunum, the anastomosis should always be made at such a distance from the duodenum as would make trouble from this cause impossible. The practice of turning the bowel around in order to make its peristaltic movements correspond with those of the stomach has no practical advantage whatever in cases of py-

loric stenosis; but, on the contrary, complicates the operation and tends to form a trap in which the intestine may become entangled. It may besides drag the wall of the stomach into a fold which may obstruct the opening into the bowel. This method of joining the viscera should be discarded.

Third.—As the orifices of communication may, if made too small, contract and become obliterated, the opening should be made at least 5 cm. in length. The effects of any resulting spur-formation will be obviated by the enteroenterostomy.

Fourth.—The safest and best method of operating is that by the elastic ligature. [J. H. G.]

6. The British Congress on Tuberculosis.
(See Abstract of *Lancet* in the *Philadelphia Medical Journal* of Aug. 13).

1.—Dudley, in speaking of **Conservative Surgery of the Uterine Appendages**, remarks that it is a well established fact that the ovaries in women can be treated surgically in an aseptic manner and that after such treatment they recover their lost functions and continue to do their full duty in the human economy for many years. Early in 1887 he began what was then experimental work in surgery on the ovaries. He has now operated upon 190 cases up to date without a single failure. Included in this number are cases in which the ovary has been completely buried in plastic exudate, in which the tube involved in the same has been completely occluded in its outer half; where the uterus has been displaced and firmly bound in such displacement; in fact, where every organ and function in the genital system of these women have been pathologic. He does not do such plastic work on the ovaries on a patient who is nearing the menopause, but only upon the young or those hopeful of bearing children. Social position influences him materially. The hard-working woman is not a fit subject for such work as a woman so situated in life as to be able to conserve her strength and, if necessary, to

take a prolonged rest. The history of hereditary taint from syphilis, tuberculosis or other diseases liable to influence the result would deter him from such work. The diseased condition of the genital organs also influences the conservative surgeon. For instance, uterine gonorrheal infection still active, syphilitic infection, still active, either secondary or tertiary, fibroid conditions that would require such extensive myomectomy that the ultimate result would be a deformed uterus, and probably occluded tubes, resulting in peritoneal complications would all contraindicate conservative surgery. In certain cases he prefers the intrauterine implantation of the ovary instead of the transplantation to the tube or abdominal wall. By this method the proper nerve supply to the ovary is not cut off, and should the ovarian tissue subsequently give trouble it is within the cavity of the uterus where it can be quickly reached with a sharp curette and removed without danger to the patient. [W. A. N. D.]

2.—Clark has made a study of **peritoneal infection and surgical peritonitis** and has arrived at the following conclusions: The peritoneum has an enormous absorbing function, being capable of taking up from 3% to 8% of the entire body-weight in an hour. Minute solid particles are carried in an incredibly short time from the peritoneal cavity through the diaphragm into the mediastinal vessels and glands, and thence into the blood-circulation by which they are quickly distributed to the abdominal organs and to the bone-marrow. The granular bodies are at first largely transported as free bodies, swept along by the lymph-current, but later the leukocytes act as the carriers. There is, normally, a force in the peritoneal cavity which carries fluids and foreign particles toward the diaphragm regardless of posture, although gravity may greatly favor or retard the current. After the introduction of micro-organisms into the peritoneal cavity there is great decrease in their number within the first hour, both through their intraperitoneal destruction and through their rapid absorption into the general system where they are dealt with. There is, therefore, no possibility of limiting free infectious matter to any part of the peritoneal cavity by mechanical means. Vigorous streptococci which remain behind develop within 6 hours a repellent or destructive quality for leukocytes, and the lethal combat is inaugurated and well under way before drainage, as ordinarily employed, can possibly exercise any beneficial action. In many cases, therefore, in which surgical drainage is employed the patient recovers in spite of and not because of it. In many cases drainage, as ordinarily employed, is superfluous or even dangerous, and the rational method is to remove all possible debris and infectious matter by thorough irrigation and then leave one liter of salt-solution in the abdominal cavity. In order to promote and hasten natural drainage, supplement this by enema of a liter of salt-solution, given while the patient is well under anesthesia and in the Trendelenburg position. [W. A. N. D.]

3.—Chevalier Jackson speaks of the rarity of primary carcinoma of the nasal fossae and the even more rare occurrence of primary carcinoma of the nasopharynx. The author has made a careful search of the literature of the subject but has been able to collect only 14 cases of primary malignant disease of the naso-pharynx. Schmidt, out of 32,997 nose and throat patients, met with but one case, although laryngeal carcinoma was seen in 75 instances. A table of the 14 primary cases is presented and discussed. In discussing the question it is said that sex plays little part as a causative factor. It is thought that irritation can play little part in producing the disease since it is found so much more frequently in the larynx than in the naso-pharynx, and yet the latter locality is much more exposed to irritation. In the majority of cases where the location was reported the growth sprung from the vault. The disease was most frequent between the years of 40 and 60. In one-half of the cases where heredity was mentioned there was found to be an hereditary predisposition in one-half of the cases. The symptoms of the disease are pain, fetor, hemorrhage, bloody discharge, and glandular involvement, each of which the author discusses in detail. [J. H. G.]

4.—Dunbar Roy discusses the question of **nasal sarcoma** and reports a case. He thinks the disease more frequent than is generally supposed. The round-cell and alveolar forms are the most common. Some authors maintain that the disease very rarely originates in the nasal passages but that it extends here from one of the continuous passages. The most frequent seat in the nasal cavity is on and around

the turbinates. The average age at which the disease occurs is about 10 years. The prognosis of sarcoma in this region does not seem to be so bad as in other parts of the body. The author's patient was a young woman of 28 years of age who had undergone frequent operations for supposed polyp. When seen by the author her case was beyond operative interference. Coley's toxins were used for two weeks with decided reactions but no change in the growth. Dowbarn's operation of ligating both external carotids was done and produced some temporary decrease in the growth. It is thought that this case illustrates the transformation of a benign into a malignant growth. At the time of the removal of the polyp in this case there was an excessive amount of bleeding and Roy thinks wherever this occurs it should create suspicion as to the nature of the growth. [J. H. G.]

5.—S. A. Oren reports an interesting case of supposed epithelioma involving the tonsil, the faucial pillar, the tongue and buccal surface. The growth occurred in a man 73 years of age. The patient was examined by a number of surgeons and was thought to present all the clinical evidences of malignant disease and a portion of the growth examined microscopically was reported to be a squamous epithelioma. The condition was considered inoperable. The patient was placed upon the iodides and local treatment applied three times a day. Hypodermatic injections of alcohol were employed for the purpose of limiting the extent of the growth. Under this combined local and constitutional treatment the patient made a satisfactory recovery, and a year after the discontinuance of the treatment showed no return of the growth. In spite of the recovery Oren is inclined to consider this a case of epithelioma. [J. H. G.]

VRATCH.

1. On Special Medical Meetings. D. N. SCHBANKOFF.
2. Genu Recurvatum. A. A. VOROBIEFF.
3. On the Influence of Common Salt on the Results of the Determination of the Organic Substances in Water by Kubel's Method. N. Ia. SCHMIDT.
4. Chaffkin's Lymph and Other Substances Elaborated by the Human Organism, Producing Immunity Against the Plague. A. F. VIGOURA.
5. A New Appliance of Engineer Iagn for Obtaining an Uninterrupted Current of Boiled and Cooled Water. S. Ia. LUBIMOFF.

2.—Will be abstracted when concluded.

3.—Schmidt found that the presence of sodium chloride in water introduces a considerable error in the determination of the organic matter by the permanganate or Kubel's method. 100 mgrms. of sodium chloride consume on an average 0.357 mgrms. of potassium permanganate or 0.098 mgrms. of oxygen. He therefore recommends Schulze's method, by which the error is practically avoided. [A. R.]

4.—Vigoura concludes his exhaustive paper with the following deductions made from a large number of experiments on monkeys and clinical observations: A. The defects of Chaffkin's lymph. (1) It confers immunity in the majority but not in all cases of preventive inoculation. No one immunized is assured against infection with and death from the plague. (2) The immunity produced by Chaffkin's lymph depends largely on personal equation of the immunized, and it is therefore impossible to determine the duration and the degree of immunity in each case. (3) The immunizing value of Chaffkin's lymph cannot be determined by the weighing method. (4) Being a fluid with an organic sediment, the lymph is liable to deterioration, although in India it has been kept for 4 months without losing in strength. (5) There is not a sufficient number of observations to enable us to determine the reaction in those cases which succumbed to the plague after the immunization and yet the necessary amount of the lymph is determined by the reaction. B. The virtues of Chaffkin's lymph. (1) It diminished the mortality from plague 10-15 times. (2) It is possible to diminish and possibly prevent an epidemic by timely and systematic use of the lymph. (3) The lymph has been tried in India on man on a large scale. It has for itself statistics and experience. Any new substance which may take the place of the lymph, owing to greater efficiency, will have to go through the same crucial tests by which the value of Chaffkin's lymph has been established. (4) With all the modifications of the tech-

nique, the method of preparation of the lymph has been rendered extremely simple, easily acquired without any considerable skill or expenditure, thus making it possible to manufacture the lymph at the very spot of the epidemic, even if the latter is removed from the centres of civilization and well equipped laboratories. Owing to the slight expense connected with it, municipalities can well undertake its manufacture. A. The defects of other substances causing immunity, produced by the organism itself. (1) These substances have no statistical data in their favor. (2) The manufacture of these substances is more difficult than is the case with Chaffkin's lymph. B. The virtues of these substances. (1) The substances of Lustig and Galleotti give promising results in laboratory experiments. (2) The determination of the active units is quite possible by weighing, especially the substance of Lustig and Galleotti. [A. R.]

5.—Lubimoff describes a new apparatus devised by Iagn for the purpose of boiling and cooling water at the same time. The apparatus consists of two cylinders with an inner cone in one of them. The inner cone receives the boiled water which is cooled by water circulating between the cone and the outer cylinder. The cylinder in which the water is boiled is provided with a bell with a valve on the upper ends of the shafts. When the water reaches 100 degrees C. the bell raises and shuts off the supply of the unboiled water. Thus the inflow of the unboiled and the outflow of boiled water takes place automatically. [A. R.]

DEUTSCHE MEDICINISCHE WOCHENSCHRIFT.

May 2, 1901.

1. The Serum Diagnosis of Tuberculosis. E. ROMBERG.
2. Concerning the Bacilli Described by Danysz, Which are Pathogenic for Rats. J. KISTER and P. KOETTGEN.
3. A Cured Case of Otogenous Meningitis. BERTELSMANN.

4. The Objects of Functional Diagnosis with Remarks Concerning the Blood as an Organ and the Regulatory Function of the Kidneys. O. ROSENBACH.
5. The Changes Taking Place in Malaria During Staining With Methylene Blue. A. IVANOFF.

1.—To be concluded.

2.—The bacilli in question are chiefly of interest in their relation to plague bacilli since the latter kill rats in large numbers and the same is said to be true of the bacilli of Danysz. Kister and Kottgen found these bacilli extremely pathogenic to rats, the pathogenicity first increasing as they were passed through animals and then, after further inoculations, decreasing. The changes caused by them in the various organs resembled those produced by plague bacilli, but there is in the authors' belief no serious danger of confusing the two organisms if the morphological and cultural peculiarities be observed. The plague bacilli are long, motionless and usually show polar staining. Those of Danysz are short, narrow, show no polar staining and have movement. In cultures with glucose Danysz's bacilli produce gas within 24 hours, the plague bacilli do not. [D. L. E.]

3.—The patient, a man of 22, had had a running ear for some time and at the time of examination had signs of beginning meningitis, or of abscess between the dura and the skull. The mastoid cells, upon operation, were found filled with pus and were cleaned out. An opening was then made posterior to the meatus and an abscess lying between the dura and bone was drained. A lumbar puncture made at the same time, showed cloudy fluid containing numerous leukocytes and from this it was decided that the man had meningitis also, but the dura was not opened as the result of the puncture was not reported until later. The man recovered completely except for a facial paralysis. [D. L. E.]

4.—Rosenbach makes some sensible remarks concerning the recent tendency to think too much of the importance of laboratory diagnosis and the diagnosis of definite organic lesions, and insists that we should devote far more attention than we do to the diagnosis of functional changes. He insists, without offering any special proof therefore, that the excretion of albumin without signs of a definite acute or chronic disease of the kidneys is not an evidence of disease but is the result of physiological action of the kidneys intended to compensate for some metabolic disturbance. He also demands that we shall look upon the blood as an organ as well as a medium of transport, not solely as the latter. [D. L. E.]

5.—The most striking characteristic of the malaria parasites under the influence of staining with methylene blue is that this stain acts chiefly on the protoplasm, in contrast with quinine which acts chiefly on the chromatin. The two are in contrast also in the form of parasites chiefly affected. Methylene blue acts chiefly on the half moon form, next on the full grown and sporulating forms and not at all on the young parasites. The direct contrary is true of quinine. With methylene blue the full-grown forms show less amoeboid movement, the protoplasm collects in balls, the chromatin stains deeply but is very granular. There is a marked achromatic zone about the chromatin. These changes appear only when the drug has been given two or three days. [D. L. E.]

CENTRALBLATT FUER CHIRURGIE.

June 1, 1901. (28 Jahrgang, No. 22).

1. Ether Narcosis. ERNST BECKER.
2. The Origin of Congenital High Position of the Scapula. W. KAUSCH.

1.—Becker has for two years added *oleum pini pumilionis* to ether just before administering the anesthetic. 20 drops to 200 g. of ether to prevent the secretion of mucus. This gives but a slight piney odor to the ether, making it less objectionable to the patient. Becker has used this mixture in about 500 cases, with uniform success. Even when bronchitis, phthisis, empyema, or senile emphysema existed, these conditions have not grown worse. In one case, a goiter in a woman of 58, mucus collected in the bronchi, lasting a few days. Since the oil of turpentine cannot do harm, its effect is even better than atropin, which is so often given before operation to prevent the accumulation of mucus. [M. O.]

2.—Kausch, who has seen five cases of congenital high position of the scapula in the past year, discovered a defect in the lower part of the trapezius muscle in three of the cases. He believes that this absence of the lower fibers of the trapezius is the cause of some cases of congenital high position of the scapula. [M. O.]

June 22, 1901. (28 Jahrgang, No. 25).

1. Immediate Cystorrhaphy After Suprapubic Cystotomy. BALACESCU.

1.—Balacescu describes the technique of Jonnesco's cystorrhaphy by imbrication, for hemorrhage cystitis. From 3 to 6 days before operation, salol or urotropin is given internally and irrigation with a solution of mercuric iodine of potassium or argentic nitrate is used. The incision is made above the pubis, and the peritoneum denuded. The bladder is then opened. Cystorrhaphy follows, with freshening of the edges, and sutures, first in the mucosa, then the muscles, and finally over the muscles. A catheter may be left in place for a week. If the patient cannot urinate voluntarily. Twelve cases treated thus are reported, 11 of which recovered rapidly. One healed very slowly. From the results he believes this to be the best operation for stone in the bladder. By this method one or two weeks in bed, not six or seven weeks, will be sufficient. [M. O.]

June 15, 1901. (28 Jahrgang, No. 24).

1. An Improved Method of Bandaging in Fractures of the Lower Extremity. HUSCHENBETT.

2. "Tulle" in the Transplantation of Skin. F. KUHN.

1.—The apparatus applied in fracture of the lower extremity generally immobilizes the knee-joint. Huschenbett's method of applying plaster of Paris bandages leaves the knee freely movable, so that walking is possible. The bandages in fractures of the hip are put on under an anesthetic. Pads are placed under the knee and under the heel. Iron bars, bent to fit the leg, attached under the heel, and movable at the knee, are kept in place by more layers of the plaster bandage. The hinges at the knee are left uncovered, though the patella is partly covered to hold the dressing in place. Walking is thus possible two days after the fracture occurs. His results have been excellent, neither dislocation nor shortening developing. A photograph is shown, of a man aged 70, thus treated for fracture of the left leg, who also had dislocated his humerus, fractured the neck of the humerus and the internal condyle of the right arm. He was walking about, a week after the accidents occurred. [M. O.]

2.—To keep the fragments in place, in transplantation

by the Thiersch method. Kuhn uses ordinary "tulle" which has been made impermeable to liquids by impregnation with a celluloid solution. This can be left in place until healing occurs. Additions can always be made and a new piece of "tulle" applied over the others. Kuhn considers the results achieved by this method far superior to those obtained with taffeta, silk, stannol, protective, etc. [M. O.]

CENTRALBLATT FUER INNERE MEDIZIN.

May 18, 1901.

- A Contribution to the Question of Antidoting Poisons (natural Immunity). MARIO CARRARA.

In the same journal (1900, No. 13) Czychlarz and Donath reported some experiments which had convinced them that strychnine combined with (or is antidoted by) certain of the tissues or body fluids. Mehtzer and Langmann (*Centralbl.*, 1900, No. 37) contended that the results were really due to slow absorption of the strychnine as a result of partially tying off the circulation in the limb into which the strychnine was injected, and were not due to an antidotal action of the tissues. Carrara claims that Czychlarz and Donath were right and that the doses given were too large to allow of a belief that the results were due to mere slow absorption. He contributes a series of experiments which he has undertaken by the same method and which showed that constricting the infected limb for several hours after giving the strychnine, allowed of the use of a dose several times the size of that which is fatal under ordinary circumstances without producing any notable symptoms. The protective influence of the procedure was much more marked in animals that had considerable natural resistance to the effects of strychnine than in those naturally very susceptible. The result was not due to slow absorption and gradual excretion, for Carrara removed both kidneys, thus doing away with the chief means of excretion of the strychnine, and saw no notable symptoms of strychnine poisoning in these animals after the procedure of Czychlarz and Donath when the same dose produced fatal poisoning under normal circumstances. Carrara also brought strychnine solutions in contact with freshly removed muscle, and then injected the enucleated muscle into animals of the same and of other species but could not see that the muscle had any antidoting effect. (Czychlarz and Donath have, however, in a second publication (*Prag. Zeitsch. f. Heilkunde*, 1901, Heft 2; *Abth. f. innere Med.*) reported that many other organs do seem to antidote strychnine when they are macerated with the drug, and that this action seems to depend upon the richness of the organ in cells, a statement which agrees well with modern theories of immunity.) [D. L. E.]

May 25, 1901.

- Carbohydrate Metabolism in Old Age. Also Some Investigations Concerning Phlaridin-diabetes.

LUDWIG v. ALDOR.

The investigations reported consisted in giving a series of 30 persons between 64 and 92 years of age doses of glucose ranging from 130 to 150 gms. on an empty stomach and observing whether alimentary glycosuria was produced thereby. The subjects were, so far as could be determined merely senile and had no known organic disease, were not alcoholics and had no other recognized predisposition to alimentary glycosuria. The results may justly be considered somewhat questionable as the amounts of glucose used were such as often cause some glycosuria in normal persons when taken on an empty stomach. 24 of the 30 persons chosen for investigation showed some glycosuria. It was notable that while glycosuria usually occurs within about an hour after giving glucose in these cases, it occurred within an hour in only two instances. In 17 it occurred only after two hours, in others only after four or five hours. Aldor suspected that the kidneys might be at fault, though the patients showed no definite sign of this, and used the phlaridin test of the renal excreting function, giving in each case a dose of 5 mg. of phlaridin subcutaneously. Those who had shown no alimentary glycosuria reacted normally to the phlaridin test. Of the others, 11 showed irregular results from the phlaridin. Aldor decides therefore, that alimentary glycosuria is very common in the aged but that it appears late after giving glucose, the latter fact being due to imperfect renal excretion. [D. L. E.]

MUENCHENER MEDICINISCHE WOCHENSCHRIFT.

June 11, 1901. (No. 24.)

1. Neutral Red Staining of the Nucleated Red Blood Cells. BETTMANN.
2. Gelatine as a Hemostatic. H. GEBELE.
3. The Pathological Condition of Drunkenness. K. HEILBRONNER.
4. The So-Called Pseudo-Myxoma of the Peritoneum. E. FRAENKEL.
5. The Treatment of Chronic Otitis Media with Hot Air. HECHT.
6. A New Pessary: The Wedge-Shaped Pessary for the Treatment of Hemorrhoids. W. SCHEFFER.

1.—Bettmann describes the following technique for the study of nucleated red blood cells. Thin sections of pith are allowed to absorb each a drop of blood, and then a small quantity of a solution of neutral red is added. The sections are placed upon a covered glass and treated in all respects as hanging drop preparations. The majority of his studies have been upon the blood of young mice, which contains great numbers of the corpuscles. When the nuclei of the red blood cells are stained, they stand out very prominently from the other structures. It is impossible therefore to confuse them with anything else. Later the lymphocytes become stained, but this does not give rise to any confusion. It is interesting to note that the nuclei are frequently placed eccentrically, and in the course of observation approach nearer and nearer the edge of the cell until sometimes they seem to project beyond it. Later they lose the stain and disappear, although the addition of more of the neutral red solution again stains them intensely. [J. S.]

2.—Gebele reports 3 interesting cases. The first, a man of 22, a hemophile, after the extraction of a molar tooth, had prolonged, uncontrollable hemorrhage. Accordingly, on the 4th day 100 ccm. of a 2% solution of gelatine were injected into the left thigh. The hemorrhage was almost entirely controlled, but as there was still a slight bloody tinge in the water used for washing, an additional injection was made on the following day. Subsequently a large abscess was opened in the submaxillary region without hemorrhage, and the patient recovered completely. The second case, a man of 28, also a hemophile, had a severe hemorrhage from the nose. Nothing seemed to check this, and on the 8th day 100 ccm. of a 2% solution were injected. The hemorrhage ceased, but the patient developed pneumonia and died 4 days later. The 3d case, a man of 48 had severe epistaxis that could not be controlled, and on the 3d day a gelatine injection was given. The hemorrhage ceased but 2 days later the injection was repeated. The patient was discharged cured. A series of experiments were made on rabbits to determine what effect injections of gelatine would have upon the amount of blood discharged from an open vessel. It was shown that in a given period of time the reduction varied from 50% to nearly 100%. This was not due merely to the anemia produced by the hemorrhage, because in control experiments the difference was practically nothing. There seems to be no doubt, therefore, that gelatine controls hemorrhage, and increases the tendency to coagulation. As, however, this testimony is only manifest after the total quantity of blood has been reduced to 1.5 of 1.4, there is no reason to suppose that gelatine injections can ever have any prophylactic action. The results of the injection are slight albuminuria; slight elevation of temperature; considerable discomfort at the point of injection, and sometimes general restlessness. In one case of hematuria evidently of renal origin, in which gelatine was given, the results were unfavorable. [J. S.]

3.—Heilbronner discusses the various conditions that may be produced by indulgence in alcohol in subjects who manifest an abnormal or morbid susceptibility to its action. He would restrict this pathological form of drunkenness to those transitory states whose symptoms exceed those of ordinary intoxication. Among these he calls attention to a state of anxiety usually characterized by a feeling of precordial discomfort, and sometimes causing the patient to commit suicide or murder. Sometimes the patients pass into a state of excessive happiness which is not the euphoria of the slightly intoxicated. In other cases there may be confusion, insanity, loss of ability to recognize position, and optic or auditory hallucinations, but movement is rarely seriously involved. Conditions are sometimes seen that resemble the convulsions of gen-

eral paresis. The attack usually occurs suddenly; sometimes after a period of sleep; sometimes it commences with a convulsion. In rare cases this stimulates general epilepsy. The duration is usually very short, sometimes only a few minutes, rarely more than a few hours. In general it terminates with a profound sleep. However in the early stages the patients are sometimes readily awakened, and the attack will then occur. Often these cases are very resistant to hyoscine. The attacks, however, may be repeated very frequently, sometimes after indulgence in very small quantities of alcohol. At other times the same patients may indulge to great excess without producing the morbid condition. The patients usually suffer from total amnesia afterward. A second group are also hallucinations, but the symptoms are very much less pronounced, and memory is not impaired. The amount of alcohol necessary to produce these attacks is sometimes very small. He reports the case of a man who, after moderate indulgence, suddenly had a convulsion and then wounded one of his companions with a knife. He retained no recollection of this condition. In another instance a student suddenly had a convulsion and then struggled violently with his companions. By the time he was brought to the hospital he had returned to his normal condition and was totally unaware of what had occurred. The paper is still unfinished. [J. S.]

4.—Fraenkel calls attention to the condition described by various authors under the name of *pseudo-myxoma peritonii*. He reports the case of a woman of 51 who, for several years had noticed enlargement of the abdomen. Three laparotomies were performed, at the first of which a tumor proceeding from the right ovary was discovered, containing an enormous amount of colloid material, a curious condition of the peritoneum was also discovered, that resembled cystic formation. A considerable quantity of yellow gelatinous fluid was removed, and the colloid cysts were found increased in number. The patient finally died, and the autopsy revealed essentially the same conditions. Microscopically the tumors resembled a cyst adenoma containing a considerable quantity of pseudo mucin. It seems likely that some of the cysts found in the peritoneum should be regarded as metastatic although in many of them the epithelial lines had disappeared as the result of some pathological condition. He reports a second case in which a somewhat similar condition was found in a man of 79, the primary situation of the tumor having been the vermiform appendix, which had undergone rupture. [J. S.]

5.—Hecht, having had a number of unfortunate experiences in his attempt to employ hot air in the middle ear, as the result of the heating of the specula that he employed, finally had constructed a fine metal tube, by means of which he was enabled to inject the hot air directly in the tympanic cavity without touching the external canal. The air is heated electrically, and the desired temperature obtained by the rheostat. The patient himself controls the air pump, and therefore can stop it as soon as the pain is unbearable. It is probable that the chief action is a thorough drying of the mucous membranes. The water produces emaciation and thus furnishes culture media for bacteria; at the same time the active hyperemia that is produced must not be overlooked. [J. S.]

6.—Scheffer has constructed a peculiar form of pessary, the essential features of which consist of a staff in the form of a double cone, which is introduced into the rectum, and a small ring which presses upon the hemorrhoids just outside. The advantage is that the sphincter has a tendency constantly to draw the instrument inward. In prolapse the hemorrhoids are replaced, and the instrument then introduced. If the external portion is hollow and connected with 2 tubes a current of warm or cold water may be applied. [J. S.]

JOURNAL DE CHIRURGIE.

April-May, 1901. (Première Année, No. 4.)

1. Cirsoïd Aneurysm of the Scalp. BROCA.
 2. Late Accidents in Cocainization of the Spinal Cord. DANDOIS.
 3. Two Cases of Hemorrhagic Papillomatous Ovarian Cyst. KEIFFER.
 4. Plastic Operations Upon the Mouth. J. LORTHOIR.
- 1.—Broca reports a cirsoïd aneurysm of the scalp in a girl 8 years and a half. Four years ago she fell, striking the right parietal bone upon the curb. Following this the

aneurysm appeared, but has not enlarged since. There was marked dilatation of the arteries and veins of the scalp, with pulsation and a noticeable thrill. These were not noted by the child at all. In spite of the probable hemorrhage, the best treatment of these arterio-venous aneurysms of the scalp is excision of the aneurysm entire. After ligation of all the vessels which branched from the aneurysm, Broca removed it, with very little hemorrhage. A week later the dressing was removed, and the child was well. The aneurysm consisted of four arteries which communicated with a large Y-shaped vein. Broca prefers treating angioma of the scalp in the same way. [M. O.]

2.—Dandolis reports an external urethrotomy performed with cocaineization of the spinal cord. This method of anesthesia was chosen on account of the poor condition of the patient. The results were excellent until the ninth day after operation, when paraplegia appeared. Then came cerebral symptoms, without fever, which persisted for a month. In three weeks more, he had wholly recovered. [M. O.]

3.—Kelfer reports two cases of hemorrhagic cysts of the ovary. One was removed by operation from a woman of 34. Its size was that of a child's head, with interstitial hemorrhages in its walls, its inner surface covered with papillae. The second tumor, which was even larger, was removed from a woman aged 54. In neither case were there any bad symptoms after operation, and both are perfectly well now. [M. O.]

4.—Before describing the operation, Lorthioir briefly reviews the embryology and history of the theories to explain the persistence of the branchial clefts. He divides these fissures into the simple fissure, the common hare-lip, unilateral, bilateral, or median; the complex fissures, with bony cleft beside hare-lip, unilateral, bilateral, or abnormal; and the palatine fissure, simple or complex cleft palate, anterior or posterior. Simple hare-lip, with or without cleft palate, is the most common. Then follow in detail descriptions of the various methods of operation, with the technique, for all forms of hare-lip. All these operations should be performed before the child reaches the age of two years. Lorthioir's results have been best from 8 to 10 years. Uranoplasty, straphylorrhaphy, and the instruments needed for the operations are also fully described. [M. O.]

JOURNAL DES PRATICIENS.

June 1, 1901. (15me. Année, No. 22).

Etherization. ALCEE DURRIEUX.

After a detailed account of the discoveries of both ether and chloroform, Durrieux states the indications and contraindications to the use of ether. The distance between the anesthetic and the mortal dose is much greater with ether than with chloroform. This fact makes ether much less dangerous than chloroform, especially when an unskilled physician is the anesthetizer. For short operations ether is excellent; in long operations, chloroform may be used after beginning with ether. Ether cannot well be used for face operations. Durrieux then describes the numerous inhalers invented. Ether should always be administered slowly, drop by drop, never in large doses. After 10 minutes the effect is seen. Ether should be added at regular intervals, 5 to 10 drops every 3 or 5 minutes. Ether increases all secretions. Then follows the treatment of the various accidents which may occur during etherization.

[M. O.]

REVUE DE MEDECINE.

May, 1901. (21me. Année, No. 51).

1. A Clinical Study of Some Infectious Diseases. II. ROGER.
2. A Comparison Between the Liver of Man and That of Pigs. CHARLES SABOURIN.
3. An Epidemic of Herpes Zoster. CHARLES DOPTEI.
4. Intermittent Nervous Troubles of Malarial Origin. BUSQUET.
5. Malarial Polyneuritis. E. BOINET.
6. Polymyositis. R. LEPINE.

1.—Will be abstracted when concluded.

2.—Sabourin has made extensive preparations of the livers of men and of pigs, which he examined in detail

histologically. He has illustrated his article with many drawings to show the conditions found. After a full description of the liver of man and of pigs, he states that the perfectly regular arrangement of the liver lobules seen in man is occasionally found in pigs. Often, however, a distinct fibrous capsule, of glissonian tissue, surrounds the separate lobules of the pig's liver. In man the capsule of Glisson forms only the outside layer of the liver covering; in the pig, the glissonian tissue often accompanies the afferent perlobular capillaries. Roger concludes that this prolongation of the fibrous tissue of the capsule of Glisson from the periphery along the afferent perlobular system, with some irregularity in the arrangement of the lobules constitute the main difference between the liver of the pig and that of man. [M. O.]

3.—Dopter reports an epidemic of herpes zoster affecting three soldiers sleeping in one room. None of the others, however, contracted it. In all three cases, sore throat, vomiting, and headache appeared first; then fever, the distinctive eruption, and pain. The lymph-glands enlarged later. After discussing the literature, Dopter states that, according to Professor Brissaud's theory, the epidemic character of herpes zoster is the expression of the elective, natural, or acquired affinity between a virus and a certain metamere of the central nervous axis, the nutrition of which has been disturbed, seen in several people, infected simultaneously or successively. Then the infection, which the eruption follows, would be epidemic. [M. O.]

4.—Busquet reports a case of malaria in a man 28, who had been a soldier in Madagascar and Algiers for three years. He had already had malaria, four separate attacks of which are described by Busquet. During these attacks paralysis of the vesical and anal sphincters occurred. There was no suspicion of hysteria, syphilis, or any infectious disease. There was at times some loss of power in the extremities, which improved upon quinine. The symptoms are believed to have been due to the presence of the malarial parasite in the capillaries of the brain and spinal cord. [M. O.]

5.—Bouinet reports a case of malarial polyneuritis in a man of 40. Both legs and arms were affected, knee jerks were absent, and sensibility diminished. There was lessened reaction of both faradic and galvanic currents. The slow appearance of the disease, its slow course, and the absence of uniformity between reflexes and gait, with the amelioration of the motor disturbance, made the diagnosis. Muscular atrophy remains marked upon the left side. There were no vasomotor symptoms. Electricity, baths, arsenic and iron constituted the treatment successfully carried out. [M. O.]

6.—Lepine reports a rare case of polymyositis which occurred in a man of 59. He presents diffuse pains localized in the muscles with edema. The spleen is enlarged. This has been called dermatomyositis or hemorrhagic polymyositis. Lepine prefers the term angiomyositis for this variety of acute polymyositis, without suppuration. [M. O.]

Chlorosis.—Professor Hayem recently (*L'Indépendance Médicale*, 1901, No. 17) discussed the subject of chlorosis. He presented a young girl of 17, saleswoman in a large department store, whose father had been tuberculous. Menstruation appeared at 13, and had been regular, but scanty in quantity. Her skin is pale, of a greenish hue, a sign of chronic anemia. She complains of palpitation, which disappears when she lies down. Over the heart a faint systolic murmur is heard, loudest at the pulmonary area. A loud venous hum is audible over the jugular veins, louder upon the left side, though usually found louder on the right. She has no headache nor edema. A few signs of rickets remain, and the groove made by her corset is plainly seen. It is in such cases that neurasthenia develops about the age of 20. Her stomach is somewhat dilated, and nephroptosis has occurred on the left side, though commonly found on the right. There are certain signs of dyspepsia, and acids are preferred. Respiration at the right apex seems slightly prolonged. Otherwise the lungs are normal. The more pronounced the symptoms of chlorosis, the less will be the danger of tuberculosis. When tuberculosis and chlorosis co-exist, they appear and develop side by side. In this case Hayem advised washing out the stomach, strict diet, and tonic constitutional treatment. [M. O.]

British Congress On Tuberculosis

FOR THE PREVENTION OF TUBERCULOSIS.

(Continued from Page 226.)

ABSTRACT OF PAPERS.

The Fight Against Tuberculosis in the Light of the Experience Gained in Successful Combat of Other Infectious Diseases. ROBERT KOCH. See Philadelphia Medical Journal, Aug. 3, 1901, pp. 1771.

The Nature and Diagnosis of Predisposition in Tuberculosis: Therapeutic Considerations. By Mons. Albert Robin, Paris. The prophylaxis of tuberculosis does not consist solely in the measures taken, either publicly or in private, against the infective agent. A study of the respiratory exchanges enables one to recognise predisposed subjects beforehand, and consequently to submit them to a hygienic and therapeutic regimen capable of modifying the functional and nutritive fault, which is the necessary antecedent condition for the development of the bacillus.

The respiratory exchanges are increased in 92% of the subjects of confirmed tuberculosis, and in 63% of those with a tuberculous heredity. Alcoholism and the different forms of overwork increase the respiratory exchanges, and are capable of creating a soil for tuberculosis in the same way as heredity.

An examination of the respiratory exchanges, therefore, enables one to make a diagnosis of tubercle in doubtful cases.

The action of different drugs and methods of treatment on the respiratory exchanges enables one to select those which are capable of modifying the soil and opens up a new mode of prophylaxis as well as of treatment in tuberculosis.

The Hereditary Arthritic Forms of Tuberculosis. By Dr. G. E. Papillon, Paris. Bearing in mind the "law of pre-tubercular hereditary reaction," which he enunciated and proved at the Thirteenth International Congress (Paris, August, 1900), the author applies that law to arthritic heredity. The existence of an arthritic diathesis, though to some extent disputed to-day, is shown by the heredity marks it produces, which are bequeathed to the descendants by the victims of any forms of that diathesis: diabetes, gout, rheumatism, asthma, etc. And if, in those descendants, any individual seems, during a part of his life, to have escaped this inheritance, the hereditary tendency will appear under the influence of any slow and hidden infection, as, for instance, the pre-tubercular infection.

In heredo-arthritic people, the pre-tubercular stage may be indicated by any arthritic manifestations, such as fits of asthma, attacks of subacute rheumatism, late appearance of what the French call "stigmata de l'arthritisme." These are not manifestations of localized tubercles, as in the case of the "tuberculous rheumatism" described ten years ago by Poncet, but only effects of the bacillary toxins.

These fits of asthma, rheumatic attacks, arthritic deviations, etc., are the symptoms of the disordered function: either of the contractility of the bronchial muscles, or of the secretion of the articular synovia, or of the nutrition of the extremities of the bone, cartilages and periarticular muscles; disorders all belonging to the great class of "sympathetic reactions to the tuberculous intoxication," which was the subject of a paper read by Dr. Papillon to the Congress of Naples (April, 1900).

The author proves that the toxins introduced into the organism by a tuberculous centre may produce the "stigmata de l'arthritisme" in predisposed individuals, as in others (otherwise predisposed by a different heredity) they may create Papillon's "Pre-tuberculous neurasthenia," or pre-tuberculous anemia, etc.

Discussion on Higher Standard of Lighting and Cleanliness.

STATE SECTION.

On the Need of a Standard of Efficient Ventilation. By Dr. Arthur Ransome, F. R. S. Consumption is a "filth disease," and flourishes in atmospheres polluted with organic matter, especially of respiratory origin.

The influence of this pollution is manifold, and is due

(1) to the presence of the bacillus of tubercle; (2) to the retention of its virulence by this organism in such atmospheres; (3) to the presence of other pathogenic organisms; (4) to its influence on the physical condition of the persons breathing such air.

Our first duty, in the prevention of consumption, must be to get rid of this "air-sewage," which causes more mortality than water-sewage. This work can only be accomplished by copious "ventilation."

The standard of ventilation hitherto fixed for dwelling rooms is 3,000 cubic feet per head per hour, in order to reduce the amount of respiratory CO₂ to two parts per 10,000.

A better method of judging the efficiency of ventilation is to take the amount of CO₂ in the air as the standard. Although it is the organic matter accompanying the CO₂ which does the harm, and although, in still air, these two ingredients are not always in proportion, owing to the non-diffusibility of the organic material, as a test of ventilation, which sweeps away both, it is a good more readily applied standard than the mere velocity of the entering, or outgoing, currents of air.

In the year 1897 a Home Office Committee, of which I was one, proposed that the CO₂ present in humidified weaving sheds should be made the standard of ventilation; and this measure was embodied in the Cotton Cloth Factories Act of 1898, with the result that a great improvement has taken place in the conditions of labor in these places. A table showing the results was exhibited.

Evidence was also given showing that the health of the operatives in these weaving sheds had greatly improved, and that, in consequence, the sickness rate had diminished.

The Act of 1898 only applied to a few thousands of male and female operatives, leaving several millions of others, who now perform their labor under the old conditions of insufficient air supply.

The paper urges that the same standard should be applied to all "work places," and anticipates that the health of the people who work in them would benefit to at least the same extent, and that the prevalence of consumption amongst them would be greatly reduced thereby.

A plea is also put in for some regulation of the ventilation of other places of public assembly, such as theatres, concert-rooms, churches, chapels, etc.

The question of cost is discussed, and it is shown that this objection need not be prohibitive.

SECTION II.

The Use of Drugs in Pulmonary Tuberculosis. By W. R. Huggard, M. A., M. D., F. R. C. P., Davis Platz. While there is no specific for pulmonary tuberculosis, various drugs influence the course of the disease favorably, always provided that they are well tolerated by the patient, and that they do not interfere with appetite or digestion.

Drugs are of less importance than fresh air, good food, and rest or exercise according to the patient's needs.

The most important point in treatment is to keep the digestion right, and to improve the nutrition. Pyrexia, while generally yielding to absolute rest in the open air, may sometimes with advantage be treated by drugs.

A tendency to hemoptysis, or to recurrent pulmonary inflammation, contraindicates the use of creosote and its derivatives, while it renders advisable the administration of the balsams, the terebinthines, and sometimes minute doses of morphine. The tendency to recurrent febrile attacks, whether from inflammation or from absorption of toxins, is diminished by arsenic, quinine, salicin and its derivatives, and strychnine.

The use of various drugs in controlling needless cough, and in augmenting, diminishing, and modifying secretion, is briefly stated, especially the value of formaldehyde vapor.

Lastly, the importance of treating syphilis as a complication is touched on, with remarks on intramuscular mercurial injections and the inhalation of iodide of ethyl.

Discussion on Internal Control.

STATE SECTION.

Notes on Tuberculosis in the Dominion of Canada. By F. Montzambert, M. D. (Edin.), F. R. C. S. E., D. C. L., Ottawa, Can. Tuberculosis in the Dominion of Canada, as elsewhere, has heretofore levied a heavy tax upon the well-being and the lives of the people. Some 8,000 deaths per annum in Canada are attributed to this disease. Some of these are, of course, amongst native-born Canadians;

others are amongst those who have brought the seeds of the disease with them from other countries.

Here, as elsewhere, the knowledge of the true nature of the disease and the methods of its spread has advanced *pari passu* with the advances of medical science. With this extension of knowledge in the medical profession have come also wiser counsels to patients and their friends, and to the public. This was, until recently only, the action of boards of health, of medical societies, of individuals, and of comparatively small local associations. This year, however, His Excellency Lord Minto, the Governor-General of Canada, has organized and set in motion a national movement for the prevention and cure of this disease. He has caused to be formed the Canadian Association for the Prevention of Tuberculosis. Of this association His Excellency is the Honorary President. Amongst its Vice-Presidents and in its Council are leading and representative men from each and every province and territory from the Atlantic to the Pacific, from the Yukon on the one side to Cape Breton on the other. The first meetings were held in Ottawa in February last, and the work of this general national movement was begun—the work of endeavoring to rouse to a sense of their danger the mass of the people, whilst at the same time a knowledge of the possibility of prevention and cure is brought home to their minds. And they are thus both encouraged and urged to take the practical measures necessary to attain the great object in view—the limitation, if not, indeed, the extinction, of this preventable disease.

This action of His Excellency has been received with grateful appreciation and hearty co-operation by all. Active steps have been, and are being taken to make the association a great educational and practical success, and high hopes are cherished of the results to be attained.

In the Dominion of Canada much of the jurisdiction in, and administration of, matters of public health falls to the different provinces and municipalities. Already some of these are moving in this matter of the prevention and cure of tuberculosis. During last year the Province of Nova Scotia passed an Act through its Legislature to empower the Province to erect, furnish and equip a sanatorium for the care and treatment of persons suffering from tubercular disease of the lungs in its earlier stage. And the Province of Ontario, in an Act respecting municipal sanatoria for consumptives, empowers, subject to the provisions of the Act, any municipality or any two or more municipalities to establish a sanatorium for the treatment of consumptives.

Of private institutions for this purpose perhaps the two largest and best known are that at Ste. Agathe des Monts, in the Laurentian range of mountains some sixty miles from Montreal, and that at Gravenhurst in the Algoma district of Ontario, within easy reach from Toronto.

If there be anything in climatic influences in the prevention and cure of tuberculosis, Canada offers a wide field for choice. She stretches from ocean to ocean, and her vast inland tablelands and mountain ranges offer all the elements of dryness, altitude, and clearness of atmosphere, with absence of strong penetrating winds, that may be desired. And this with a variety of grandeur of scenery and full opportunities for out-of-door sports, hunting, fishing, etc., for those who seek them; and for all, the pleasant summer weather and the dry and invigorating cold in winter render life and rest out of doors a possibility and a benefit at all seasons of the year by night as well as by day.

With such conditions as these available we may fairly hope that when the people can be educated up to the realization of the truth as to the communicability of tuberculosis, and the means of controlling its diffusion and spread, a marked diminution, both in frequency and in its mortality, may speedily be attained.

The Value of Tuberculin in Diagnosis and Treatment. By Prof. McCall Anderson. The subject is dealt with under three heads.

I.—*Is it safe to use it?*—The answer being in the affirmative, if it is employed in suitable cases, if the dose is not too large or too rapidly increased, and if the intervals between successive injections are not too short.

II.—*What is its value in diagnosis?*—It is enormous, and it is a curious anomaly that, while it is recognized as a very certain test for tuberculosis in cows, it is rarely used by medical men in the case of human beings.

III.—*What is its therapeutic value?*—In the early stages

of phthisis it is calculated to yield good results, but in more advanced cases, when a large extent of lung substance has become implicated, it must be used with caution, if at all. But in external tuberculosis it is almost invariably beneficial, and in many cases removes the existing manifestations. It is true that relapses are very apt to occur, if it is not borne in mind that there are two factors concerned in the production of tuberculosis; (a) the tubercle bacillus, and (b) the soil suitable for its growth and development; so that in addition to attacking the former with tuberculin, we must endeavor to counteract the latter with the aid of pure air, generous diet, and other recognized anti-strumous measures.

The Morphological and Physical Variations of the Bacillus Tuberculosis and its Relations: (a) to other Acid-fast Bacilli, (b) to the Ray Fungus and other Streptothricaceae. By William Bulloch, London.

I. So far as is known, the Bacillus Tuberculosis discovered by Koch is the only immediate cause of all forms of human tuberculosis.

II. In the majority of cases the micro-organism is met with in the form of slender rods, which frequently show clear spaces in their interior.

III. Under certain conditions at present imperfectly understood, the micro-organism may show filaments, true dichotomous branching and club formation, and, in the tissues, especially in experimental tuberculosis, it may assume a radiate arrangement—characters which from a taxonomic point of view bring it into close relation with a large group of micro-organisms variously designated Streptothricaceae, Oospora, Nocardiaceae, and more recently Actinomycetes (Lachner-Sandoval).

IV. According to all experience, the tubercle bacillus is an aerobic facultative parasite which grows extremely slowly outside the body, and for its growth requires a relatively high temperature, the minimal and maximal limits of which are 29°C. and 42°C. This fact is against the supposition that the tubercle bacillus multiplies extra corporally, at least in temperate climates.

V. In general, cultures are difficult to obtain, and are best prepared by growing the organism upon relatively complicated media, such as blood serum. The addition of glycerine to all media undoubtedly favors the development and luxuriance of the cultures. In the presence of this substance, however, good growths can be obtained in vegetable media, such as potato (Pawlowsky, Lubinsky, and others). It is also possible to obtain growths on media which contain no proteid material, the carbon and nitrogen demands of the organism being fulfilled respectively by ammonia salts and glycerine. Hitherto in such simple media it has not been possible to replace the glycerine by other allied compounds (Proskauer and Fleck).

VI. With ordinary hydro-alcoholic solutions of basic anilin colors, the tubercle bacillus is stained with extreme difficulty and imperfectly. If certain substances (anilin, para-toluidin, meta-toluidin, benzaldehyde, carbolic acid—in practice the latter is chiefly used) are added to the basic dyes, the penetrating power of the latter for the tubercle bacillus is increased in high degree, and on subsequent treatment with mineral acids (33% nitric acid, 25% sulphuric acid) the color remains in the bacilli, so that they stand out prominently from other objects in whose association they may be. This "fastness" towards acids (Säurefestigkeit), discovered by Ehrlich, has had a great influence on the development of the study of tuberculosis, and at the present day the microscopic diagnosis is made with this method alone.

VII. The acid-fastness is, however, not specific to the tubercle bacillus, but is also possessed by a considerable number of other bacilli, some of which are pathogenic for man (Bacillus Leprieux), some for animals. In recent times the number of these have been considerably increased, and although they have been found as saprophytes, and capable of living at relatively low temperatures, they may produce tubercle-like diseases in animals.

VIII. The microscopic diagnosis alone is not sufficient to differentiate the true tubercle parasite from other "acid-fast" organisms. There is every reason to believe that the bacillus of human and bovine tuberculosis, are identical. The bacillus of avian tuberculosis presents points of difference, but these are not differences of species. There exists a group of acid-fast, tubercle-like bacilli wide-

ly distributed in Nature. The identity or nonidentity of these with Koch's bacillus is not proven.

IX. In any case, a microscopic diagnosis of Koch's bacillus, especially in objects which are from their nature and source liable to contamination with other acid-fast bacilli, is not decisive by itself.

X. Even the application of alcohol subsequent to acid is not capable of differentiating the tubercle bacillus from others like it. Some tubercle-like bacilli may be as *saurefast* and *alcoholfast* as Koch's bacillus.

XI. Contrary to former beliefs, the acid-fastness is not due to the presence of *fat* in the bacillus, as, after complete removal of this substance the bacilli are still acid- and alcohol fast. The acid-fastness is due to a body of the nature of a wax (Aronson) which can be extracted by acid-alcohol-ether, boiling chloroform, boiling benzene. This wax in itself is powerfully acid-fast, but is unstainable by fat stains. (Sudan III, and Ponceau R.)

XII. Besides wax and fat, which are present in relatively large amounts, the tubercle bacillus is composed of proteids (important among which is a variety of nucleic acid, described as tuberculinic acid—Ruppel) and salts (with phosphates predominating). After the removal of all proteids, wax and fat, a substance remains which contains a considerable quantity of nitrogen and from its reactions is probably chitin or some allied body.

XIII. No certain facts are known of the possession or non-possession by the tubercle bacillus or other acid-fast bacilli of true endospores. Although the tubercle bacillus is more resistant to injury than non-sporing microbes, it is much less resistant than true endospores.

A Study of Heredity in its Relation to Immunity and Selective Activity in Tuberculosis. By Dr. Herbert Maxon King, New York. In a paper, of which the foregoing is the title, the author has embodied the results of carefully recorded observations in two hundred and forty-two cases of tuberculosis occurring in his own practice, where opportunity for close personal study into the immediate family histories and such other features of the several cases as would throw light upon the present inquiry were exceptional. He has endeavored to prove, in so far as was possible by the limited number of cases under observation, that a history of tuberculosis in the parents instead of predisposing an individual to the disease, confers to a certain extent an immunity to it—an immunity which of course is but relative and not sufficiently protective, yet such as to deserve a more thorough and unprejudiced attention than has thus far been accorded the subject. After briefly summarizing in the usual way the family histories of his series of cases, the author devotes the chief space of his paper to an analysis of the progress of the disease in one hundred and three fatal cases out of the total two hundred and forty-two. Of these fatal cases he finds that seventy-six occurred among individuals of non-tubercular parentage. The average duration of the disease in these cases, from its earliest evidence to death, was 2.93 years. The other twenty-seven fatal cases occurred among individuals of tubercular parentage. The average duration of disease in these cases was 4.01 years; more than a year longer than in the former class, and this, it is to be observed, among a class which for obvious reasons may be fairly presumed to have contracted the infection at a time considerably more remote from the date of death than would be the case among those of non-tubercular parentage.

He cites the instances of tuberculous outbreaks among negroes and Indians of the Far West of non-tubercular heredity, in which resistance to the disease is lowest, and where a rapidly fatal termination is the almost unexceptional rule; and this is in a climate to which are sent the more immune whites suffering from this disease, as a therapeutic measure.

The conclusions arrived at, by the author's observations, are:—

First, the percentage of consumptives having a tubercular parentage, is actually smaller than that having a non-tubercular parentage, and much smaller than would be more than accounted for by the additional danger of infection to which the former class is subjected; and

Second, tuberculosis in the parents render to no inconsiderable extent an immunity to the disease in the offspring, as is shown by increased resistance to the progress of the disease and increased tendency to recover among this class.

The Open-Air Treatment in Institutions and in Nursing Homes. By E. Syme Thompson, M. D., F. R. C. S. Dr. Syme Thompson in this communication, compares the value of "Nursing Homes," where a few cases can be admitted with the "Sanatorium" treatment. He points out the often insurmountable difficulty of carrying out the open-air treatment in the homes of the patients, giving reasons for this want of success. He shows that balconies and shelters are superior to rooms, even when the windows are actually removed, and the percentage of carbon dioxide is the same as in the open air. The therapeutic value of *wind* is considered in some detail.

The paper contains suggestions and details of treatment as regulated: 1st, by incessant observations of temperature (charts, by which the rectal and mouth temperatures are compared, demonstrate the insufficiency of mouth temperatures as guides for treatment); 2nd, by watchful consideration of the respiratory movements; 2nd, by discriminating attendance to the digestive system.

Whilst affection of the larynx is a late manifestation of tubercular disease, pharyngeal affection is an early, often the earliest symptom. Indeed, in many cases tubercle appears thus to gain access to the system, and it is in cases of tubercular pharyngitis, prior to the development of lung disease, that careful local and constitutional treatment in a Nursing Home often proves of the greatest value.

Whilst foreign health resorts retain their value in many cases, English resorts, and especially those at the seaside, are of equal value in some, and of even greater value in other conditions.

The Paper concludes with a condensed record of a series of cases from which the deduction is reached. In rapid cases (galloping consumption) Nursing Home treatment is the best that can be found. In many slight cases the evil is arrested in these Homes more successfully than in other ways, and in advanced cases of long standing lasting benefit is often thus secured.

The Role of the Nasal Fossae in the Prophylaxis and Treatment of Pulmonary Tuberculosis. By Dr. Maurice Mignon, Nice. When we consider the question of the prophylaxis of tuberculosis, we must recognize the fact that contagion takes place chiefly through the air. Air is the vehicle by which the microbes invade the organism far more frequently than foods, which can be sterilized by cooking. When the air is still infective, in spite of the use of spittoons, in spite of the practice of disinfection, in spite of every precaution intended to prevent the spread of the disease, the nasal fossae are still capable of arresting the danger that threatens us. The microbes that enter with the air are, in a large measure, arrested by the cilia of the nasal vestibule and by the very extensive and very irregular surface of the mucous membrane. One may thus recognize the bactericidal function of the nasal mucus, although it has been questioned by some authors. Clinical experience teaches, indeed, that the nasal fossae are much more resistant to tuberculosis than the rest of the respiratory tract, and even than the bucco-pharyngeal cavity. Insufficient nasal permeability (nasal obstruction from malformations or septal ridges, from hypertrophic or congestive rhinitis, from cysts, vegetations, adenoids, etc.), should therefore be reckoned among the dangers of tuberculous infection.

From the point of view of treatment the state of the nasal fossae is of equal importance. As the nose allows more air to enter than the mouth, nasal insufficiency results in deficient oxidation of the blood, and everyone knows how necessary oxygen is to the tuberculous. Entering by the mouth the air brings with it harmful microbes, which, accompanied by dust, favor the malady. Moreover, this air, insufficient and injurious, is unmodified, either in temperature or in pressure; it provokes bucco-pharyngeal, laryngeal and tracheo-bronchial inflammations which impede the action of treatment.

It is therefore absolutely necessary that we should be satisfied that patients presenting themselves for examination (especially those disposed to tuberculosis, and those who are themselves tuberculous) are not suffering from any cause of nasal insufficiency. If any defect is present it should be remedied, and we should enjoin the patients to breathe solely by the nose as soon as they are able, for in this habit often plays a part. Instruction on the latter point should be included in the general advice which one makes a point of disseminating amongst all classes of the population.

SLOW PULSE WITH SPECIAL REFERENCE TO
STOKES—ADAMS DISEASE.*

D. ROBERT T. EDES, M. D.,

a Boston

Since our late associate, D. W. Prentiss was so kind as to call my attention to his patient with an extremely slow pulse, whom he showed to this society in 1899 and in whose case I had the opportunity to make a post-mortem examination, I have added somewhat to my own experience and have also looked over a not inconsiderable amount of literature which has accumulated upon the subject since that time.

CASE I. Mrs. Rosetta M., aet. 50. Housewife; born in New Hampshire, of N. E. parentage. Her father died of pulmonary hemorrhage; her mother from a fall during pregnancy. She has been an invalid since the birth of a child 25 years ago. She has had one miscarriage and frequent headaches. One year ago these were intense. In the Worcester City Hospital, a short time last year, short of breath, emotional, fainted several times. In January fell on the street. Two years ago had sciatica, lately treated by Dr. Samuel Breck for uterine trouble. Fainted one day while at work and has fallen in the house several times since then. Entered the Boston City Hospital, June 3, 1897. While in bed has sinking spells, feels as if she were falling. Appetite fair. Bowels constipated. Temperature 101; pulse 56; respiration 22. Patient said that her nervous condition was due largely to shock and grief at death of her daughter's child of scarlet fever. She was pale, anemic, and nervous, the pupils equal, reacting to light and accommodation. The tongue moist with a white coat. The pulse regular, 40, of poor strength and volume. The heart's area not enlarged, action irregular, sounds very weak. At times between pulsations are heard sometimes one, sometimes two or three slight sounds as of incomplete beats. Pulse synchronous with heart. At times a soft systolic murmur replacing first sound at apex, slight roughening of first sound at aortic area. Lungs and abdomen negative. Knee jerks normal; no ankle clonus; hyperesthesia of extremities.

June 4: Felt faint during the afternoon, dull and heavy headache, pain about the heart and throbbing of head. Several slight sinking spells during early part of the night. About 1 A. M., screamed and apparently lost consciousness. Night nurse could not feel pulse. House Officer called and gave subcut. of ether, patient roused, confused, but recognized house officer. Pulse very weak and slow. Quiet the rest of the night. Next day felt weak and very dull. In regard to attack of night before said that she was not unconscious, but felt powerless, screamed because she felt herself sinking. Felt as if oppressed by great weight. Dark blurring of eyes, was conscious of the night nurse's presence and heard them discussing as to whether she was dead. Recognized House Officer when he came. On this day the pulse went down to twenty.

June 11: Patient says that she can feel pulsations of her heart in her left hand and arm when grasping anything with this hand. Pulse and heart sounds synchronous, no evidence of organic disease. Patient feels very weak.

19. Patient up dressed and out on the piazza. Pulse still weak and slower than apex beat.

22, 1897: Urine 500 c.c.; acid 1012; urea 1.39 o/o; Ind. -n. Alb. sl. poss. trace. Sugar -o.

Sediment: Occasional abnormal blood globule; squamous epithelium; occasional small hyaline and finely granular cast; few blood and fat globules; few renal cells. J. H. Ogden.

21. Pulse 35 to 48. Has had slight chill; attack of vertigo every few days. Pulse at such times scarcely perceptible, does not lose consciousness when in attacks. Never any convulsions.

29. Had four spells yesterday, given brandy and nitro-glycerine, attacks of semi-unconsciousness preceded by headache, blurring of vision, feelings as if sinking down into hole. She is somewhat paler than usual at such times

and her eyes are closed. After attack feels weak; head aches badly and she is much exhausted, pupils dilated and pulse slow (18-20) but improves with stimulation. She bathes her clothes daily and spends an hour on the piazza. Attacks generally come on in P. M. Premonitory symptoms warn her to go to bed.

July 11: Head heavy. Tenderness in left side of head.

July 12: Condition much improved; pulse still slow. Di. more relieved. Diagnosis: Hysteria, myocarditis.

The chart kept during this time gives the temperature on the day of entrance at 101 and for three days after as normal. After this it was not taken. The pulse after two observations at twenty rose somewhat and ranged even about twenty-five to forty-eight, being for a considerable part of the time between 35 and 45. The respirations were from 20 to 25.

Admitted to the Adams Nervine Asylum on July 11. Her application paper gave nothing additional except the statement of Dr. Breck, that she had lately had a thorough pelvic examination under ether without anything definite being found.

Height, 5-1; weight, 146. Early history unimportant, except headaches. About seven weeks ago headaches were worse and she had pain in the left groin. Seven weeks ago fell several times during the day with short spells of unconsciousness; the next day twice. When she entered she had not lost much flesh, her manner was calm, but she was sleeping badly, usually from 1 to 5 or 6 hours, seldom the latter. Her dreams were not especially bad and she had no morbid fears or hallucinations; her appetite was deficient and she was constipated. She was pale, with a somewhat puffy complexion. She was frequently having the sinking spells. There was no enlarged cardiac dulness. Sounds nearly normal, the first sound rather long, occasionally with something like reduplication or interruption, occasionally very slight beat just after second. Says she feels her heart beat in her head and limb. Counted the head beats herself while I held the radial pulse. They were synchronous. Her hand goes to sleep. When she has the sinking spells, the whole arm is involved. There is a burning sensation over the heart and there is dyspnea when she lies upon her left side. The sphygmographic tracings have a long, flat top and gradual decline without diastolic. She continued in about the same condition for several weeks with the pulse very slow, much of the time being 25 or 26, and at the paroxysms becoming imperceptible. The blood was never counted, but color index was not below that of the average female. There was no abnormality in the white corpuscles. The urine when measured, was below the normal in quantity, contained no albumin and only the normal amount of indoxyl.

The eyegrounds normal. There is a beating in the back of the head nearly all the time. The feeling coming from the back to top of head coincides with the spells. When seen in or soon after the attacks her pulse would be imperceptible or very slow, she said that in some of them she became unconscious, but this apparently did not last long. There were sometimes several days when there would be none. Her sleep improved somewhat as regards the average number of hours per night. The record of medication consists chiefly in cardiac stimulants with no hypnotics.

September 10: Patient has had several slight spells of faintness occurring during the day time; has been in bed ever since entrance, but has bed rest, wants to get up; has complained of rheumatic pains in muscles of both legs; pulse 32 to 36.

September 18: On the 11th and 12th, attacks (patient said afterwards that she was not conscious during these attacks) during which pulse scarcely felt at the wrist; duration 15 to 30 minutes. On the 16th, about 9 o'clock, had fainting spell, aroused dazed and confused. Again, about 1 A. M., called nurse and said that she felt she was going to have another attack and while nurse was at the telephone, patient screamed loudly several times, awakening and frightening all the patients. Nurse found her with eyes staring, pupils dilated, tossing herself about the bed and tearing her hair. No dyspnea, face very pale. Nurse tried to keep her quiet by holding her, assisted by night watchman, who had been attracted by the cries. Assistant called, but found patient quiet, in apparent unconscious state. Ammonia to nostrils and subcut. ether given. Pulse 16 to 18, could scarcely be counted on account of weakness. Later on nurse applied faradic battery;

*Read before the Association of American Physicians, Washington, May 1.

The interne of the service informed me that he could hear none recently.

CASE IV.—In September, 1899, I saw with Dr. Edson, of Roxbury, a bank cashier, æt. about 60. For years he had worked very hard, with very little vacation. Last winter he was restless and twitching and he could not walk up hill as well as he used to. For years he had had occasional blind headaches. Last May he lost consciousness and fell. In July he had another severe attack but after that none for a considerable time until he got hot and tired in the cars. Since then several severe ones and a great many less so. In the severe ones he loses consciousness and twitches in face and legs. In the slighter ones there is no twitching and no complete loss of consciousness. In the severe ones his color becomes white and then red, or red and then white, his wife stating the latter and others the former. During my visit he said that he had several slight ones but I could observe nothing except that after some of them there seemed a little longer interval in the heart's beats and then two or three closer together. The pulse at the wrist was 29 to 31, mostly regular, of good force and tension. The arteries appeared smooth and elastic at the wrist and the temple. The heart's impulse was not exaggerated nor the dullness increased. There was a strong double beat (the normal sounds) synchronous with the radial pulse. Between them one faint beat which sometimes seemed to be more developed, so that the pulse was apparently quicker, but this was not frequent enough to greatly increase the number of beats per minute. There was a systolic murmur, loudest at the base. This examination was made without a stethoscope.

Through the courtesy of the patient and of Dr. Edson I had the opportunity of examining him again last February, that is about a year and a half after the first examination. Dr. Edson informed me in his note that "for a year his pulse has kept at 28 and is full and perfectly regular with none of the faltering it showed when you saw him. His lapses of consciousness grew less frequent until May last, since which date he has had none." I found that he had not only had no losses of consciousness, but not even any faintness or dyspnea unless on going up-stairs too fast. He walks out and even cuts a little wood. He is somewhat deaf, varying at times, but always the most on the right side, where there is a slight trace of facial paralysis. I examined his heart with the phonendoscope, but through his clothing, and thought that I could at times make out a lesser beat after the principal one.

A pulse considerably below the average is much more likely to call the attention of the physician and the patient than one above it, as being much less common and less easily accounted for by any of the usual conditions which raise it, exercise, nervous excitement and especially fever. The fact that so many cases of it have been reported shows, indeed, that it strikes the practitioner as an unusual circumstance. The statement of Gossett Brown (*Brit. Med. J.*, 1879, Dec. 27), however, who says that in many thousands of cases in both hospital and private practice he had seen two cases of slow pulse is an extreme one. He evidently refers to the remarkably or phenomenally slow pulse, of which both of his cases are instances.

Riegel (*Ztschr. f. Klin. Med.*, 1890, p. 221), taking 60 as the figure of the normal pulse, finds among 4,484 men and 3,083 women, with a total of 7,567; 710, 334, and 1041 cases of slow pulse respectively; but of all these, however, he says, that but 47 were connected with diseases of the organs of circulation.
